PRINTED AT MARTIN BILLING, SON, AND CO.'S STEAM-PRESS OFFICES,
LIVERY STREET.

INDEX.

1864.

	PAGE
Annual Report	1
Blast Furnaces, Construction of, in Cleveland district, by J. G. Beckton	249
Blast Furnaces, Working and Capacity of, by C. Cochrane	163
Boiler, Cast Iron Steam, Harrison's, by Z. Colburn	61
Coal Cutting Machine, by T. Levick	272
Coalfield, Glasgow, principal Seams of Coal and Ironstone in, by W. Moore	229
Cranes, Traversing, at Crewe Locomotive Works, by J. Ramsbottom	44
Dredgers, Steam, on the Clyde, by A. Duncan	147
Locomotives, Distribution of Weight on Axles of, by J. Robinson	92
Memoirs of Members deceased in 1863	13
Puddling Iron by Machinery, by H. Bennett	298
Pump, Horizontal V, by J. J. Birckel	33
Stone Breaking Machine, for Breaking Limestone and Ore, by J. Lancaster	20
Subjects for Papers	5
Tools, Heavy, for general Engineering and Iron Shipbuilding Work, by J. Fletcher	189
Water Works, Loch Katrine, for supply of Glasgow, Mechanical Appliances of, by J. M. Gale	123

COUNCIL, 1864.

President.

ROBERT NAPIER, . . . Glasgow.

Past-Presidents.

SIR WILLIAM G. ARMSTRONG, Newcastle-on-Tyne.

JAMES KENNEDY, . . . Liverpool.

JOHN PENN, . . . London.

JOSEPH WHITWORTH, . . . Manchester.

Vice-Presidents.

CHARLES F. BEYER, . . . Manchester.

EDWARD A. COWPER, . . . London.

ROBERT HAWTHORN, . . . Newcastle-on-Tyne.

SAMPSON LLOYD, . . . Wednesbury.

HENRY MAUDSLAY, . . . London.

JOHN RAMSBOTTOM, . . . Crewe.

Council.

ALEXANDER ALLAN, . . . Perth.

JOHN ANDERSON, . . . Woolwich.

FREDERICK J. BRAMWELL, . . . London.

DANIEL K. CLARK, . . . London.

WILLIAM CLAY, . . . Liverpool.

CHARLES COCHRANE, . . . Dudley.

JOHN FERNIE, . . . Leeds.

SIR CHARLES FOX, . . . London.

GEORGE HARRISON, . . . London.

THOMAS HAWKSLEY, . . . London.

EDWARD HUMPHRYS, . . . London.

EDWARD JONES, . . . Wednesbury.

WALTER MAY, . . . Birmingham.

C. WILLIAM SIEMENS, . . . London.

CHARLES P. STEWART, . . . Manchester.

Treasurer.

HENRY EDMUNDS,

Birmingham and Midland Bank, Birmingham.

Secretary.

WILLIAM P. MARSHALL,

Institution of Mechanical Engineers.

81 Newhall Street, Birmingham.

LIST OF MEMBERS,

WITH YEAR OF ELECTION.

1864.

LIFE MEMBERS.

1858. Bower, John Wilkes, Lancashire and Yorkshire Railway, Engineer's Office,
Manchester.
1852. Brogden, Henry, Sale, near Manchester.
1858. Fletcher, Henry Allason, Lowca Engine Works, Whitehaven.
1857. Haughton, S. Wilfred, 62 Lower Baggot Street, Dublin.
1854. Lloyd, George Braithwaite, Messrs. Lloyds, High Street, Birmingham.
1853. Maudslay, Henry, Cheltenham Place, Lambeth, London, S.
1856. Napier, Robert, West Shandon, Helensburgh, near Glasgow.
1848. Penn, John, The Cedars, Lee, Kent, S.E.
1864. Tennant, Charles, The Glen, Innerleithen, near Edinburgh.
1863. Wicksteed, Thomas, 8 Torquay Terrace, Headingley, near Leeds.

MEMBERS.

1861. Abel, Charles Denton, 20 Southampton Buildings, London, W.C.
1848. Adams, William Alexander, Midland Works, Birmingham.
1859. Adamson, Daniel, Newton Moor Iron Works, Hyde, near Manchester.
1861. Addenbrooke, George, Rough Hay Furnaces, Darlaston, near Wednesbury.
1851. Addison, John, 6 Delahay Street, Westminster, S.W.
1858. Albaret, Auguste, Engine Works, Liancourt, Oise, France.
1847. Allan, Alexander, Locomotive Superintendent, Scottish Central Railway,
Perth.
1856. Allen, James, Cambridge Street Works, Manchester.
1859. Alton, George, Midland Railway Works, Derby.
1861. Amos, Charles Edwards, Grove Works, Southwark, London, S.E.
1856. Anderson, John, Assistant Superintendent, Royal Gun Factories, and
Inspector of Machinery to the War Department, Royal Arsenal,
Woolwich, S.E.
1856. Anderson, William, Erith Iron Works, Erith, Kent, S.E.
1862. Angus, Robert, Locomotive Superintendent, North Staffordshire Railway,
Stoke-upon-Trent.

1858. Appleby, Charles Edward, Renishaw Iron Works, near Chesterfield.
1859. Armitage, William James, Farnley Iron Works, Leeds.
1863. Armstrong, John, Timber Works, 20 North Bridge Street, Sunderland.
1857. Armstrong, Joseph, Locomotive Superintendent, Great Western Railway, Swindon.
1858. Armstrong, Sir William George, Elswick, Newcastle-on-Tyne.
1857. Ashbury, James Lloyd, Openshaw Works, near Manchester.
1848. Ashbury, John, Openshaw Works, near Manchester.
1858. Atkinson, Charles, Fitzalan Steel Works, Sheffield.
1860. Bailey, Samuel, Mining Engineer, The Pleck, near Walsall.
1860. Barclay, John, Bowling Iron Works, near Bradford, Yorkshire.
1860. Barker, Paul, Old Park Iron Works, Wednesbury.
1863. Barlow, Edward, Messrs. Dobson and Barlow, Machine Works, Bolton.
1862. Barrow, Joseph, 93 Argyle Terrace, Bristol Street, Hulme, Manchester.
1862. Barton, Edward, 1 Market Street, Manchester.
1847. Barwell, William Harrison, Eagle Foundry, Northampton.
1859. Bastow, Samuel, Cliff House Iron Works, West Hartlepool.
1860. Batho, William Fothergill, Messrs. Nettlefold and Chamberlain, Smethwick Screw Works, Birmingham.
1859. Beacock, Robert, Victoria Foundry, Leeds.
1860. Beale, William Phipson, 27 Victoria Street, Westminster, S.W.
1848. Beattie, Joseph, Locomotive Superintendent, London and South Western Railway, Nine Elms, London, S.
1859. Beck, Edward, Messrs. Neild and Co., Dallam Iron Works, Warrington.
1862. Beckett, Henry, Mining Engineer, Upper Penn, Wolverhampton.
1864. Beckton, James George, Whitby.
1858. Bell, Isaac Lowthian, Clarence Felling and Wylam Iron Works, Newcastle-on-Tyne.
1857. Bellhouse, Edward Taylor, Eagle Foundry, Hunt Street, Oxford Street, Manchester.
1854. Bennett, Peter Duckworth, Spon Lane Iron Foundry, Westbromwich.
1861. Bessemer, Henry, 4 Queen Street Place, New Cannon Street, London, E.C.
1847. Beyer, Charles F., Messrs. Beyer Peacock and Co., Gorton Foundry, Manchester.
1861. Binns, Charles, Mining Engineer, Clay Cross, near Chesterfield.
1863. Birckel, John James, Vauxhall Foundry, Liverpool.
1847. Birley, Henry, Haigh Foundry, near Wigan.
1856. Blackburn, Isaac, Witton Park Iron Works, Darlington.
1851. Blackwell, Samuel Holden, Dudley.
1862. Blake, Henry Wollaston, Messrs. James Watt and Co., 18 London Street, London, E.C.

1862. Blyth, Alfred, Steam Engine Works, Fore Street, Limehouse, London, E.
 1863. Boeddinghaus, Julius, Messrs. Heinrich Boeddinghaus and Sons, Elberfeld, Prussia.
 1862. Bouch, Thomas, 78 George Street, Edinburgh.
 1858. Bouch, William, Shildon Engine Works, Darlington.
 1847. Bovill, George Hinton, 24 Duke Street, Westminster, S.W.
 1862. Boyd, Nelson, Belfast Foundry, Donegal Street, Belfast.
 1854. Bragge, William, Atlas Steel and Iron Works, Sheffield.
 1854. Bramwell, Frederick Joseph, 35A Great George Street, Westminster, S.W.
 1856. Bray, Edwin, Nevill Holt, near Market Harborough.
 1861. Brierly, Henry, 27 Southampton Buildings, London, W.C.
 1848. Broad, Robert, Horseley Iron Works, near Tipton.
 1863. Brown, Henry, Metropolitan Carriage and Wagon Company, Saltley Works, Birmingham.
 1847. Brown, James, Jun., Messrs. James Watt and Co., Soho Foundry, near Birmingham.
 1850. Brown, John, Atlas Steel and Iron Works, Sheffield.
 1855. Brown, John, Mining Engineer, Barnsley.
 1853. Brown, Ralph, Patent Shaft Works, Wednesbury.
 1863. Brown, William Steel, Edinburgh and Glasgow Railway, Cowlairst, Glasgow.
 1858. Burn, Henry, Midland Railway, Locomotive Department, Derby.
 1856. Butler, Ambrose Edmund, Kirkstall Forge, Leeds.
 1863. Butler, Arthur, Surdah, Radshye, Lower Bengal, India : (or care of Walter Butler, 1 Westminster Chambers, Victoria Street, Westminster, S.W.)
 1859. Butler, John, Old Foundry, Stanningley, near Leeds.
 1859. Butler, John Octavins, Kirkstall Forge, Leeds.
 1857. Cabry, Joseph, 3 Colbeck Terrace, Tynemouth, near North Shields.
 1847. Cabry, Thomas, North Eastern Railway, York.
 1847. Cammell, Charles, Cyclops Steel and Iron Works, Sheffield.
 1864. Campbell, David, 20 Castle Street, Liverpool.
 1860. Cannell, Fleetwood James, Old Park Iron Works, Wednesbury.
 1860. Carbutt, Edward Hamer, Vulcan Iron Works, Thornton Road, Bradford, Yorkshire.
 1862. Carpmael, William, 24 Southampton Buildings, London, W.C.
 1856. Carrett, William Elliott, Sun Foundry, Leeds.
 1864. Carrington, William Thomas, 18 Great George Street, Westminster, S.W.
 1858. Carson, James Irving, Locomotive Superintendent, West Hartlepool Harbour and Railway, Stockton-on-Tees.
 1849. Chamberlain, Humphrey, 3 St. John's, Wakefield.
 1857. Chrimes, Richard, Brass Works, Rotherham.
 1854. Clark, Daniel Kinnear, 11 Adam Street, Adelphi, London, W.C.

1859. Clark, George, Monkwearmouth Engine Works, Sunderland.
 1862. Clark, James, 4 Corporation Street, Manchester.
 1859. Clay, William, Mersey Steel and Iron Works, Sefton Street, Liverpool.
 1863. Clayton, Robert, Soho Foundry, Preston.
 1847. Clift, John Edward, Durnford Place, Coventry Road, Birmingham.
 1860. Clunes, Thomas, Worcester Engine Works, Worcester.
 1858. Cochrane, Charles, Woodside Iron Works, near Dudley.
 1860. Cochrane, Henry, Ormesby Iron Works, Middlesbrough.
 1854. Cochrane, John, Woodside Iron Works, near Dudley.
 1864. Coddington, William, Ordnance Cotton Mill, Blackburn.
 1847. Coke, Richard George, Mining Engineer, Chesterfield.
 1864. Colburn, Zerah, 7 Gloucester Road, Regent's Park, London, N.W.
 1853. Cooper, Samuel Thomas, Leeds Iron Works, Leeds.
 1860. Cope, James, Mining Engineer, Pensnett, near Dndley.
 1848. Corry, Edward, 8 New Broad Street, London, E.C.
 1857. Cortazzi, Francis James, Locomotive Superintendent, Great Indian Peninsula Railway, Bombay, India : (or care of Thomas Dyson Hornby, 3 Brunswick Street, Liverpool.)
 1860. Coulthard, Hiram Craven, Park Iron Works, Blackburn.
 1864. Cowans, John, St. Nicholas and Woodbank Iron Works, Carlisle.
 1847. Cowper, Edward Alfred, 35A Great George Street, Westminster, S.W.
 1862. Cox, Samuel H. F., 3 East Parade, Sheffield.
 1863. Craig, Andrew, Rock Ferry, Birkenhead.
 1847. Crampton, Thomas Russell, 12 Great George Street, Westminster, S.W.
 1858. Crawhall, Joseph, St. Ann's Wiro and Hemp Rope Works, Newcastle-on-Tyne.
 1857. Criswick, Theophilus, Lydbrook Deep Level Collieries, near Ross.
 1863. Crow, George, Messrs. R. Stephenson and Co., South Street, Newcastle-on-Tyne.
 1864. Crowe, Edward, Tees Side Iron Works, Middlesbrough.
 1858. Cubitt, Charles, 3 Great George Street, Westminster, S.W.

 1864. Daglish, George Heaton, St. Helen's Foundry, St. Helen's.
 1864. Darby, Charles E., Brymbo Iron Works, near Wrexham.
 1863. Davy, Alfred, Park Iron Works, Sheffield.
 1849. Dawes, George, Milton and Elsecar Iron Works, near Barnsley.
 1860. Dawes, William Henry, Bromford Iron Works, Westbromwich.
 1861. Dawson, Benjamin, South Hetton, near Fence Houses.
 1862. Deakin, William, Monmer Lane Iron Works, Willenhall, near Wolverhampton.
 1857. De Bergue, Charles, Strangeways Iron Works, Manchester.
 1858. Dees, James, Whitehaven.

1858. Dempsey, William, 26 Great George Street, Westminster, S.W.
1864. Dewhurst, John, Wadsley Bridge Iron and Steel Works, near Sheffield.
1859. Dixon, John, Railway Foundry, Bradford, Yorkshire.
1861. Dixon, Thomas, Low Moor Iron Works, near Bradford, Yorkshire.
1857. Douglas, George K., Messrs. R. Stephenson and Co., South Street, Newcastle-on-Tyne.
1857. Dove, George, St. Nicholas and Woodbank Iron Works, Carlisle.
1847. Dubs, Henry, Glasgow Locomotive Works, Glasgow.
1857. Dunlop, John Macmillan, Marlborough Street, Oxford Street, Manchester.
1854. Dunn, Thomas, Windsor Bridge Iron Works, Manchester.
1864. Dunn, Thomas Edward, Jumna Bridge, East Indian Railway, Allahabad, India: (or care of R. Dunn, Howick, near Alnwick).
1861. Dutton, Charles, Bromford Iron Works, Westbromwich.
1860. Dyson, George, Tudhoe Iron Works, near Ferryhill.
1859. Eassie, Peter Boyd, Saw Mills, High Orchard, Gloucester.
1858. Easton, Edward, Grove Works, Southwark, London, S.E.
1856. Eastwood, James, Railway Iron Works, Derby.
1862. Elder, John, Messrs. Randolph Elder and Co., Centre Street, Glasgow.
1859. Elliot, George, Houghton-le-Spring, near Fence Houses.
1860. Elwell, Thomas, Messrs. Varrall Elwell and Poulot, 9 Avenue Trudaine, Paris.
1853. England, George, Hatcham Iron Works, London, S.E.
1861. Esson, William, Engineer, Cheltenham Gas Works, Cheltenham.
1864. Etienne, Antonin, Engineer, Cordova and Seville Railway, Seville, Spain.
1857. Evans, John Campbell, Morden Iron Works, East Greenwich, S.E.
1848. Everitt, George Allen, Kingston Metal Works, Adderley Street, Birmingham.
1864. Everitt, William Edward, Kingston Metal Works, Adderley Street, Birmingham.
1857. Fairlie, Robert Francis, 56 Gracchurch Street, London, E.C.
1861. Fearnley, Thomas, Globe Works, Hall Lane, Bradford, Yorkshire.
1854. Fernie, John, Clarence Iron Works, Leeds.
1861. Field, Joshua, Cheltenham Place, Lambeth, London, S.
1864. Fleet, Thomas, Crown Boiler Works, Westbromwich.
1861. Fleetwood, Daniel Joseph, Metal Rolling Mills, Icknield Port Road, Birmingham.
1847. Fletcher, Edward, Locomotive Superintendent, North Eastern Railway, Gateshead.
1857. Fletcher, James, Messrs. W. Collier and Co., 2 Greengate, Salford, Manchester.

1859. Fogg, Robert, 17 Park Street, Westminster, S.W.
 1861. Forster, Edward, Spon Lane Glass Works, near Birmingham.
 1849. Forsyth, John C., North Staffordshire Railway, Stoke-upon-Trent.
 1864. Foster, Edward Henry, Old Park Iron Works, Wednesbury.
 1861. Foster, Sampson Lloyd, Old Park Iron Works, Wednesbury.
 1847. Fothergill, Benjamin, 27 Cornhill, London, E.C.
 1847. Fowler, John, 2 Queen Square Place, Westminster, S.W.
 1857. Fowler, John, Steam Plough Works, Leeds.
 1847. Fox, Sir Charles, 8 New Street, Spring Gardens, London, S.W.
 1864. Frankish, John, 1 Lord's Chambers, Corporation Street, Manchester.
 1859. Fraser, John, 18 York Place, Leeds.
 1853. Fraser, Joseph Boyes, Alma Place, Kenilworth.
 1856. Freeman, Joseph, 22 Cannon Street, London, E.C.
 1864. Frost, Thomas, Canal Street Iron Works, Derby.
 1852. Froude, William, Elmsleigh, Paignton, Torquay.
1862. Galton, Capt. Douglas, R.E., War Office, Pall Mall, London, S.W.
 1847. Garland, William S., Messrs. James Watt and Co., Soho Foundry, near Birmingham.
1848. Gibbons, Benjamin, Hill Hampton House, near Stourport.
 1856. Gilkes, Edgar, Tees Engine Works, Middlesbrough.
 1862. Godfrey, Samuel, Messrs. Bolckow and Vaughan's Iron Works, Middlesbrough.
1848. Green, Charles, Tube Works, Leek Street, Birmingham.
 1861. Green, Edward, Jun., 3 Bank Street, Exchange, Manchester.
 1858. Greenwood, Thomas, Albion Works, Armley Road, Leeds.
 1857. Gregory, John, Engineer, Portuguese National Railway South of Tagus, Barriero, near Lisbon, Portugal.
1860. Grice, Frederic Groom, Stour Valley Works, Spon Lane, Westbromwich.
1861. Haden, William, Dixon's Green, Dudley.
 1861. Haggie, Peter, Hemp and Wire Rope Works, Gateshead.
 1864. Halkett, John Craigie, Cramond Iron Works, Edinburgh.
 1863. Hall, Joseph, Gratz Iron Works, Gratz, Styria, Austria.
 1857. Hall, William, Ashted Varnish and Colour Works, 167 Dartmouth Street, Birmingham.
1860. Hamilton, Gilbert, Messrs. James Watt and Co., Soho Foundry, Birmingham.
1858. Harding, John, Beeston Manor Iron Works, Leeds.
 1859. Harman, Henry William, Canal Street Works, Manchester.
 1856. Harrison, George, Canada Works, Birkenhead.
 1858. Harrison, Thomas Elliot, 1 Westminster Chambers, Victoria Street, Westminster, S.W.

1863. Hartas, Isaac, Rosedale Iron Mines, near Pickering, Yorkshire.
1858. Haswell, John A., North Eastern Railway, Locomotive Department, Gateshead.
1861. Hawkins, William Bailey, 24 Budge Row, Cannon Street, London, E.C.
1856. Hawksley, Thomas, 30 Great George Street, Westminster, S.W.
1848. Hawthorn, Robert, Forth Banks, Newcastle-on-Tyne.
1848. Hawthorn, William, Forth Banks, Newcastle-on-Tyne.
1862. Haynes, Thomas John, Calp Foundry, North Front, Gibraltar.
1860. Head, John, Messrs. Ransomes and Sims, Orwell Works, Ipswich.
1858. Head, Thomas Howard, Teesdale Iron Works, Stockton-on-Tees.
1853. Headly, James Ind, Eagle Works, Cambridge.
1857. Healey, Edward Charles, 163 Strand, London, W.C.
1862. Heath, William J. W., Assistant Engineer, Ceylon Railway, Colombo, Ceylon : (or care of John J. Heath, 105 Vyse Street, Birmingham.)
1864. Heathfield, Richard, Lion Galvanising Works, Birmingham Heath, Birmingham.
1860. Heaton, George, Royal Copper Mint, Icknield Street East, Birmingham.
1858. Hedley, John, 4 High Swinburn Place, Newcastle-on-Tyne.
1864. Hetherington, William Isaac, Vulcan Works, Pollard Street, Manchester.
1864. Hide, Thomas C., 46 Fenchurch Street, London, E.C.
1863. Hind, Roger, Scotland Bank Iron Works, Warrington.
1862. Hingley, Samuel, Hart's Hill Iron Works, near Brierley Hill.
1858. Hodgson, Robert, North Eastern Railway, Newcastle-on-Tyne.
1852. Holcroft, James, Shut End, Brierley Hill.
1863. Holt, Frank, Gorton Foundry, Manchester.
1848. Homersham, Samuel Collett, 19 Buckingham Street, Adelphi, London, W.C.
1860. Hopkins, James Innes, Tees Side Iron Works, Middlesbrough.
1856. Hopkinson, John, London Road Iron Works, Manchester.
1858. Hopper, George, Houghton-le-Spring Iron Works, near Fence Houses.
1858. Horsley, William, Jun., Whitehill Point Iron Works, Percy Main, near Newcastle-on-Tyne.
1851. Horton, Joshua, Ætna Works, Smethwick, near Birmingham.
1858. Hosking, John, Gateshead Iron Works, Gateshead.
1864. Howard, Eliot, 84 Upper Whitecross Street, London, E.C.
1860. Howard, James, Britannia Iron Works, Bedford.
1860. Howe, William, Clay Cross Coal and Iron Works, near Chesterfield.
1861. Howell, Joseph Bennett, Hartford Steel Works, Sheffield.
1862. Huber, Peter Emile, Vogelhutte, Zurich, Switzerland.
1864. Hulse, William Wilson, The Grove, Withington, Manchester.
1847. Humphrys, Edward, Deptford Pier, London, S.E.
1859. Hunt, James P., Corngreaves Iron Works, Corngreaves, near Birmingham.
1856. Hunt, Thomas, Tudela and Bilbao Railway, Bilbao, Spain : (or 3 Stanley Place, Preston.)

1864. Hutchinson, Edward, Skerne Iron Works, Darlington.
1863. Hutton, Walter Stuart, Prospect Works, Hunslet Lane, Leeds.
1857. Inshaw, John, Engine Works, Morville Street, Birmingham.
1859. Jackson, Matthew Murray, Messrs. Escher Wyss and Co., Engine Works, Zurich, Switzerland.
1847. Jackson, Peter Rothwell, Salford Rolling Mills, Manchester.
1861. Jackson, Robert, Ætna Steel Works, Sheffield.
1860. Jackson, Samuel, Cyclops Steel and Iron Works, Sheffield.
1858. Jaffrey, George William, Hartlepool Iron Works, Hartlepool.
1856. James, Jabez, 28a Broadwall, Stamford Street, Lambeth, London, S.
1855. Jeffcock, Parkin, Mining Engineer, Midland Road, Derby.
1861. Jeffcock, Thomas William, Mining Engineer, 18 Bank Street, Sheffield.
1863. Jeffreys, Edward A., Low Moor Iron Works, near Bradford, Yorkshire.
1857. Jenkins, William, Locomotive Superintendent, Lancashire and Yorkshire Railway, Miles Platting, Manchester.
1861. Jessop, Sydney, Park Steel Works, Sheffield.
1861. Jessop, Thomas, Park Steel Works, Sheffield.
1854. Jobson, John, Derwent Foundry, Derby.
1863. Johnson, Bryan, Flookersbrook Foundry, Chester.
1847. Johnson, James, North Staffordshire Railway, Engineer's Office, Stoke-upon-Trent.
1861. Johnson, Samuel Waite, Locomotive Superintendent, Edinburgh and Glasgow Railway, Cowlares, Glasgow.
1861. Jones, Alfred, Ettingshall Iron Works, Bilston.
1861. Jones, David, Engineer, Rumney Railway, Machen, near Newport, Monmouthshire.
1847. Jones, Edward, Old Park Iron Works, Wednesbury.
1857. Jones, John Hodgson, 26 Great George Street, Westminster, S.W.
1853. Joy, David, Cleveland Engine Works, Middlesbrough.
1857. Kay, James Clarkson, Phoenix Foundry, Bury, Lancashire.
1857. Kendall, William, Locomotive Superintendent, Blyth and Tyne Railway, Percy Main, near Newcastle-on-Tyne.
1863. Kennan, James, Agricultural Implement Works, 19 Fishamble Street, Dublin.
1847. Kennedy, James, Cressington Park, Aigburth, Liverpool.
1857. Kennedy, Lt.-Colonel John Pitt, Engineer, Bombay Baroda and Central Indian Railway; 10 Liverpool Street, New Broad Street, London, E.C.
1863. Kennedy, John Pitt, Bombay Baroda and Central Indian Railway; 10 Liverpool Street, New Broad Street, London, E.C.

1848. Kirkham, John, 109 Euston Road, London, N.W.
1847. Kirtley, Matthew, Locomotive Superintendent, Midland Railway, Derby.
1864. Kirtley, William, Midland Railway, Locomotive Department, Derby.
1859. Kitson, Frederick William, Monkbridge Iron Works, Leeds.
1848. Kitson, James, Airedale Foundry, Leeds.
1859. Kitson, James, Jun., Monkbridge Iron Works, Leeds.
1863. Knight, Thomas, 130 Bradford Street, Birmingham.
1862. Knott, Joseph, Pennington Cotton Mill, Leigh, near Manchester.

1863. Lancaster, John, Kirkless Hall Coal and Iron Works, near Wigan.
1863. Latham, Ernest, 28 Clarence Square, Gosport.
1860. Law, David, Phoenix Iron Works, Glasgow.
1857. Laybourn, John, Isca Foundry, Newport, Monmouthshire.
1856. Laybourn, Richard, Locomotive Superintendent, Monmouthshire Railway and Canal Company, Newport, Monmouthshire.
1860. Lea, Henry, 33 Waterloo Street, Birmingham.
1862. Lee, J. C. Frank, 30 Parliament Street, Westminster, S.W.
1860. Lee, John, Midland Railway, Locomotive Department, Derby.
1863. Lees, Samuel, Jun., Park Bridge Iron Works, Ashton-under-Lyne.
1863. Leigh, Evan, Miles Platting, Manchester.
1858. Leslie, Andrew, Iron Ship Building Yard, Hebburn Quay, Gateshead.
1856. Levick, Frederick, Cwm-Celyn Blaina and Coalbrook Vale Iron Works, near Newport, Monmouthshire.
1860. Lewis, Thomas William, Plymouth Iron Works, Merthyr Tydvil.
1864. Lindsley, George, Great Western Railway, Locomotive Department, Paddington, London, W.
1856. Linn, Alexander Grainger, 2 Queen Square Place, Westminster, S.W.
1857. Little, Charles, Staveley Coal and Iron Works, Staveley, near Chesterfield.
1863. Lloyd, Edward R., Albion Tube Works, Nile Street, Birmingham.
1862. Lloyd, John, Lilleshall Iron Works, Oakengates, near Wellington, Shropshire.
1847. Lloyd, Sampson, Old Park Iron Works, Wednesbury.
1864. Lloyd, Sampson Zachary, Old Park Iron Works, Wednesbury.
1852. Lloyd, Samuel, Old Park Iron Works, Wednesbury.
1862. Lloyd, Wilson, Old Park Iron Works, Wednesbury.
1863. Loam, Matthew Hill, Engineer, Gas and Water Works, Nottingham.
1856. Longridge, Robert Bewick, Steam Boiler Assurance Company, 67 King Street, Manchester.
1859. Lord, Thomas Wilks, 2a Alfred Street, Boar Lane, Leeds.
1861. Low, George, Millgate Iron Works, Newark.
1854. Lynde, James Gascoigne, Town Hall, Manchester.

1864. Macfarlane, Walter, Saracen Foundry, Glasgow.
1856. Mackay, John, Mount Hermon, Drogheda.
1864. Macnab, Archibald Francis, Fazeley Street Wire Mills, Birmingham.
1859. Manning, John, Boyne Engine Works, Hunslet, Leeds.
1862. Mansell, Richard Christopher, South Eastern Railway, Carriage Department, Ashford.
1862. Mappin, Frederick Thorpe, Sheaf Works, Sheffield.
1857. March, George, Union Foundry, Leeds.
1856. Markham, Charles, Staveley Coal and Iron Works, Staveley, near Chesterfield.
1848. Marshall, Edwin, Britannia Carriage Works, Birmingham.
1862. Marshall, James, Bunker Hill, Fence Houses.
1859. Marshall, William Ebenezer, Sun Foundry, Leeds.
1847. Marshall, William Prime, 81 Newhall Street, Birmingham.
1859. Marten, Edward Bindon, Engineer, Stourbridge Water Works, 13 High Street, Stourbridge.
1853. Marten, Henry, Parkfield Iron Works, near Wolverhampton.
1857. Martindale, Capt. Ben Hay, R.E., War Office, Pall Mall, London, S.W.
1854. Martineau, Francis Edgar, Globe Works, Cliveland Street, Birmingham.
1864. Martley, William, Locomotive Superintendent, London Chatham and Dover Railway, Longhedge Works, Wandsworth Road, London, S.
1857. Masselin, Armand, 16 Rue Dauphine, Paris.
1853. Mathews, William, Corbyn's Hall Iron Works, near Dudley.
1848. Matthew, John, Messrs. John Penn and Co., Marine Engineers, Greenwich, S.E.
1847. Matthews, William Anthony, Sheaf Works, Sheffield.
1864. Maudslay, Thomas Henry, Cheltenham Place, Lambeth, London, S.
1861. May, Robert Charles, 3 Great George Street, Westminster, S.W.
1857. May, Walter, Suffolk Works, Berkley Street, Birmingham.
1859. Maylor, William, East Indian Iron Company, Beypoor, India : (or care of E. J. Burgess, Abchurch Chambers, Abchurch Yard, London, E.C.)
1847. McClean, John Robinson, 23 Great George Street, Westminster, S.W.
1864. McEwen, Lawrence Thomson, Ormesby Iron Works, Middlesbrough.
1860. McKenzie, James, Well House Foundry, Leeds.
1859. McKenzie, John, Worcester Engine Works, Worcester.
1862. McPherson, Hugh, Engineer, Gloucester Gas Works, Gloucester.
1863. Meek, Sturges, Resident Engineer, Lancashire and Yorkshire Railway, Manchester.
1858. Meik, Thomas, Engineer to the River Wear Commissioners, Sunderland.
1857. Menelaus, William, Dowlais Iron Works, Merthyr Tydvil.
1857. Metford, William Ellis, Flook House, Taunton.
1847. Middleton, William, Vulcan Iron Foundry, Summer Lane, Birmingham.

1862. Miers, Francis C., Stoneleigh Lodge, Grove Road, Clapham Park, London, S.
1864. Miers, John William, 74 Addison Road, Kensington, London, W.
1853. Miller, George Mackay, Great Southern and Western Railway, Dublin.
1862. Millward, John, Union Chambers, High Street, Stourbridge.
1856. Mitchell, Charles, Iron Ship Building Yard, Low Walker, Newcastle-on-Tyne.
1858. Mitchell, James, 3 Church Terrace, Higher Trimere, Bickenhead.
1861. Mitchell, Joseph, Worsbrough Dale Colliery, near Barnsley.
1859. Moor, William, Engineer, Hetton Colliery, Hetton, near Fence Houses.
1864. Moore, Sampson, North Foundry, Williams Street, Clarence Dock, Liverpool.
1864. Morgan, Joshua Llewelyn, Woodside, Cwmbran, near Newport, Monmouthshire.
1849. Morrison, Robert, Ouseburn Engine Works, Newcastle-on-Tyne.
1858. Mountain, Charles George, Suffolk Works, Berkeley Street, Birmingham.
1863. Muir, William, Britannia Works, Manchester.
1857. Munz, George Frederick, French Walls, near Birmingham.
1859. Murphy, James, Railway Works, Newport, Monmouthshire.
1858. Murray, Thomas H., Engine Works, Chester-le-Street, near Fence Houses.
1863. Musgrave, John, Jun., Globe Iron Works, Bolton.
1848. Napier, John, Vulcan Foundry, Glasgow.
1861. Naylor, John William, Wellington Foundry, Leeds.
1858. Naylor, William, Great Indian Peninsula Railway, 3 New Broad Street, London, E.C.
1863. Neilson, Walter Montgomerie, Hyde Park Locomotive Works, Glasgow.
1860. Nettlefold, Joseph Henry, Screw Works, Broad Street, Birmingham.
1856. Newall, James, East Lancashire Railway, Carriage Department, Bury, Lancashire.
1862. Newton, William Edward, 66 Chancery Lane, London, W.C.
1858. Nichol, Peter Dale, Locomotive Superintendents, East Indian Railway, Allahabad, India: (or care of Anthony Nichol, 22 Quay, Newcastle-on-Tyne.)
1850. Norris, Richard Stuart, 272 Upper Parliament Street, Liverpool.
1864. Ommanney, Frederick Francis, New Bridge Foundry, Adelphi Street, Salford, Manchester.
1847. Owen, William, Phoenix Works, Rotherham.
1859. Paquin, Jean François, Locomotive Superintendents, Madrid Saragossa and Alicante Railways, Madrid, Spain.
1860. Parkin, John, Harvest Lane Steel Works, Sheffield.

1847. Peacock, Richard, Messrs. Beyer Peacock and Co., Gorton Foundry, Manchester.
1848. Pearson, John, 1 Manchester Buildings, 7 Old Hall Street, Liverpool.
1859. Peet, Henry, London and North Western Railway, Locomotive Department, Wolverton.
1861. Perkins, Loftus, 3 Oberhafenstrasse, Hamburg: (or care of A. M. Perkins, 6 Francis Street, Regent's Square, London, W.C.)
1856. Perring, John Shae, 104 King Street, Manchester.
1863. Perry, Thomas J., Highfields Engine Works, Bilston.
1860. Peyton, Edward, Bordesley Works, Birmingham.
1856. Piggott, George, Birmingham Heath Boiler Works, Birmingham.
1854. Pilkington, Richard, Jun., 10 Coburg Place, Upper Kennington Lane, London, S.
1859. Pitts, Joseph, Old Foundry, Stanningley, near Leeds.
1859. Platt, John, Hartford Iron Works, Oldham.
1862. Player, John, Norton, near Stockton-on-Tees.
1861. Plum, Thomas William, 3 East India Avenue, London, E.C.
1856. Pollard, John, Midland Junction Foundry, Leeds.
1860. Ponsonby, Edward Vincent, Engineer, Great Western Railway, Worcester.
1852. Porter, John Henderson, Ebro Works, Tividale, near Tipton.
1861. Porter, Robert, Ebro Works, Tividale, near Tipton.
1864. Potts, Benjamin Langford Foster, 150 Camberwell Grove, London, S.
1851. Potts, John Thorpe, 150 Camberwell Grove, London, S.
1856. Preston, Francis, Ancoats Bridge Works, Ardwick, Manchester.
1862. Rake, Alfred Stansfield, Royal Victoria Dockyard, Passage West, near Cork.
1864. Ramage, Robert, Locomotive Superintendent, Midland Great Western Railway, Dublin.
1847. Ramsbottom, John, Locomotive Superintendent, London and North Western Railway, Crewe.
1860. Ransome, Allen, Jun., Messrs. Worssam and Co., King's Road, Chelsea, London, S.W.
1862. Ransome, Robert James, Orwell Works, Ipswich.
1862. Ravenhill, John R., Glass House Fields, Ratcliff, London, E.
1859. Rennie, George Banks, 39 Wilton Crescent, Belgrave Square, London, S.W.
1862. Reynolds, Edward, Don Steel Works, Sheffield.
1863. Richards, Edwin, Nantyglo Iron Works, near Newport, Monmouthshire.
1856. Richards, Josiah, Abersychan Iron Works, Pontypool.
1863. Richardson, Edward, Engineer, Lyttelton, New Zealand.
1858. Richardson, Thomas, Hartlepool Iron Works, Hartlepool.
1859. Richardson, William, Hartford Iron Works, Oldham.
1863. Rigby, Samuel, Cock Hedge Mill, Warrington.

1848. Robertson, Henry, Great Western Railway, Shrewsbury.
1859. Robinson, John, Messrs. Sharp Stewart and Co., Atlas Works, Manchester.
1853. Ronayne, Joseph P., 4 Harbour Hill, Queenstown.
1856. Rouse, Frederick, Great Northern Railway, Locomotive Department, Leeds.
1857. Routledge, William, New Bridge Foundry, Adelphi Street, Salford, Manchester.
1860. Rumble, Thomas William, 6 Broad Street Buildings, New Broad Street, London, E.C.
1847. Russell, John Scott, 20 Great George Street, Westminster, S.W.
1863. Ryder, William, Bark Street, Bolton.
1859. Sacré, Charles, Locomotive Superintendent, Manchester Sheffield and Lincolnshire Railway, Gorton, near Manchester.
1864. Said, Colonel M., Bey, Ottoman Embassy, Bryanston Square, London, W.
1859. Salt, George, Saltaire, near Bradford, Yorkshire.
1864. Samuda, Joseph D'Aguilar, Iron Ship Building Yard, Isle of Dogs, Poplar, London, E.
1848. Samuel, James, 26 Great George Street, Westminster, S.W.
1857. Samuelson, Alexander, 27 Cornhill, London, E.C.
1857. Samuelson, Martin, Scott Street Foundry, Hull.
1861. Sanderson, George Grant, Parkgate Iron Works, Rotherham.
1864. Sanderson, John, Locomotive Superintendent, Whitehaven Cleator and Egremont Railway, Moor Row, near Whitehaven.
1860. Schneider, Henry William, Ulverstone Hæmatite Iron Works, Barrow, near Ulverstone.
1858. Scott, Joseph, Messrs. R. & W. Hawthorn, Forth Banks, Newcastle-on-Tyne.
1861. Scott, Walter Henry, Mauritius Railways, Locomotive Department, Port Louis, Mauritius: (or care of Joseph Reid, 49 Arundel Square, London, N.)
1864. Seddon, John, 31 King Street, Wigan.
1857. Selby, George Thomas, Smethwick Tube Works, Birmingham.
1850. Shanks, Andrew, 6 Robert Street, Adelphi, London, W.C.
1863. Sharp, Henry, Bolton Iron and Steel Works, Bolton.
1862. Sharpe, William John, 1 Victoria Street, Westminster, S.W.
1864. Shaw, Duncan, Mining Engineer, Cordova, Spain.
1856. Shelley, Charles Percy Bysshe, 21 Parliament Street, Westminster, S.W.
1861. Shepherd, John, Union Foundry, Hunslet Road, Leeds.
1859. Shuttleworth, Joseph, Stamp End Iron Works, Lincoln.
1851. Siemens, Charles William, 3 Great George Street, Westminster, S.W.
1862. Silvester, John, Messrs. George Salter and Co., Spring Balance Works, Westbromwich.

1862. Simpson, William, Conservative Club, St. James' Street, London, S.W.
 1847. Sinclair, Robert, Great Eastern Railway, Stratford, London, E.
 1857. Sinclair, Robert Cooper, 19 Temple Street, Birmingham.
 1859. Slater, Isaac, Gloucester Wagon Company, Gloucester.
 1853. Slaughter, Edward, Avonside Engine Works, Bristol.
 1854. Smith, George, Wellington Road, Dudley.
 1860. Smith, Henry, Brierley Hill Iron Works, Brierley Hill.
 1858. Smith, Isaac, 36 Lancaster Street, Birmingham.
 1860. Smith, John, Brass Foundry, Traffic Street, Derby.
 1857. Smith, Josiah Timmis, Ulverstone Hæmatite Iron Works, Barrow, near
 Ulverstone.
 1859. Smith, Matthew, Caledonia Wire Mills, Halifax.
 1860. Smith, Richard, Berry Hill, Lichfield.
 1857. Smith, William, 19 Salisbury Street, Adelphi, London, W.C.
 1863. Smith, William Ford, Gresley Iron Works, Ordsal Lane, Salford,
 Manchester.
 1857. Snowdon, Thomas, 147 High Street, Stockton-on-Tees.
 1859. Sokoloff, Capt. Alexander, Engineer, Russian Imperial Service, Steam
 Marine Department, Cronstadt, Russia: (or care of Messrs. W. Collier
 and Co., 2 Greengate, Salford, Manchester.)
 1863. Somerville, Wallace Cochrane, 15 Vassal Road, North Brixton, London, S.
 1858. Sørensen, Bergerius, Engineer-in-Chief, Royal Norwegian Navy Depart-
 ment, Horten Dockyard, Norway: (or care of Messrs. Tottie and Sons,
 2 Alderman's Walk, Bishopsgate Street, London, E.C.)
 1859. Spencer, John Frederick, 3 St. Nicholas Buildings, Newcastle-on-Tyne.
 1853. Spencer, Thomas, Old Park Works, near Shiffnal.
 1854. Spencer, Thomas, Newburn Steel Works, Newcastle-on-Tyne.
 1864. Spittle, Thomas, Cambrian Iron Foundry, Newport, Monmouthshire.
 1862. Stableford, William, Oldbury Carriage Works, near Birmingham.
 1859. Stewart, Charles P., Messrs. Sharp Stewart and Co., Atlas Works,
 Manchester.
 1851. Stewart, John, Blackwall Iron Works, Russell Street, Blackwall,
 London, E.
 1864. Stokes, James Polliott, Resident Engineer, West Shropshire Mineral
 Railway, Meole Brace, Shrewsbury.
 1857. Stokes, Lingard, 36 Carey Street, Lincoln's Inn Fields, London, W.C.
 1863. Storey, John Henry, Knott Mill Brass and Copper Works, Little Peter
 Street, Manchester.
 1862. Strong, Joseph F., Resident Engineer, East Indian Railway, Cawnpore,
 India.
 1861. Sumner, William, 21 Clarence Street, Manchester.
 1860. Swindell, James Evers, Parkhead Iron Works, Dudley.

1864. Swindell, James Swindell Evers, Cradley Iron Works, near Brierley Hill.
1859. Swingler, Thomas, Victoria Foundry, Litchurch, near Derby.
1861. Tangye, James, Cornwall Works, Clement Street, Birmingham.
1859. Tannett, Thomas, Victoria Foundry, Leeds.
1861. Taylor, George, Clarence Iron Works, Leeds.
1858. Taylor, James, Britannia Engine Works, Cleveland Street, Birkenhead.
1862. Taylor, John, Mining Engineer, 6 Queen Street Place, Upper Thames Street, London, E.C.
1862. Taylor, Richard, Mining Engineer, 6 Queen Street Place, Upper Thames Street, London, E.C.
1864. Thomas, Thomas, Clyde House, Canton, Cardiff.
1857. Thompson, John Taylor, Messrs. R. and W. Hawthorn, Forth Banks, Newcastle-on-Tyne.
1857. Thompson, Robert, Haigh Foundry, near Wigan.
1862. Thompson, William, Spring Gardens Engine Works, Newcastle-on-Tyne.
1852. Thomson, George, Crookhay Iron Works, Westbromwich.
1861. Thwaites, Robinson, Vulcan Iron Works, Thornton Road, Bradford, Yorkshire.
1862. Tijou, William, 9 Great George Street, Westminster, S.W.
1861. Tipping, Isaac, H. M. Gun Carriage Manufactory, Madras, India : (or care of H. Tipping, Bridgewater Foundry, Patricroft, near Manchester.)
1862. Tolmé, Julian Horn, 1 Victoria Street, Westminster, S.W.
1863. Tomlinson, Edward, Miles Platting Works, Elm Street, Manchester.
1857. Tomlinson, Joseph, Jun., Locomotive Superintendent, Taff Vale Railway, Cardiff.
1856. Tosh, George, Locomotive Superintendent, Maryport and Carlisle Railway, Maryport.
1860. Townsend, Thomas C., 16 Talbot Chambers, Shrewsbury.
1863. Townsend, William, West Orchard, Coventry.
1862. Troward, Charles, Great Northern Railway, Locomotive Department, Doncaster.
1856. Truss, Thomas, Great Western Railway, Carriage Department, Chester.
1859. Turner, Edwin, Bowling Iron Works, near Bradford, Yorkshire.
1856. Tyler, Capt. Henry Wheatley, R.E., Railway Department, Board of Trade, Whitehall, London, S.W.
1862. Upward, Alfred, Engineer, Chartered Gas Company, 146 Goswell Street, London, E.C.
1862. Vavasseur, Josiah, Bear Lane, Southwark Street, London, S.E.
1856. Vernon, John, Iron Ship Building Yard, Brunswick Dock, Liverpool.
1861. Vickers, Thomas Edward, Don Steel Works, Sheffield.

1856. Waddington, John, New Dock Iron Works, Leeds.
 1856. Waddington, Thomas, New Dock Iron Works, Leeds.
 1863. Wakefield, John, Great Southern and Western Railway, Locomotive Department, Dublin.
 1864. Walker, Bernard Peard, Junction Cut Nail Works, Wolverhampton.
 1861. Walker, John G., Netherton Iron Works, near Dudley.
 1847. Walker, Thomas, Patent Shaft Works, Wednesbury.
 1863. Walker, William Hugill, Wicker Iron Works, Sheffield.
 1863. Wallace, William, Superintending Engineer, Montreal Ocean Steam Ship Company, Liverpool.
 1864. Warden, Walter Evers, Phoenix Bolt and Nut Works, Glover Street, Birmingham.
 1856. Wardle, Charles Wetherell, Boyne Engine Works, Hunslet, Leeds.
 1852. Warham, John R., Iron Works, Burton-on-Trent.
 1862. Watkins, Richard, Canal Iron Works, Millwall, London, E.
 1862. Webb, Francis William, London and North Western Railway, Locomotive Department, Crewe.
 1862. Webb, Henry Arthur, Bretwell Hall Iron Works, near Stourbridge.
 1860. Weild, William, Queen's Chambers, Market Street, Manchester.
 1862. Wells, Charles, Moxley Iron Works, near Bilston.
 1862. Westmacott, Percy G. B., Elswick Engine Works, Newcastle-on-Tyne.
 1856. Wheeldon, Frederick R., Highfields Engine Works, Bilston.
 1864. White, Isaiah, Messrs. Portilla and White, Engineers and Iron Ship Builders, Seville, Spain.
 1859. Whitham, James, Perseverance Iron Works, Kirkstall Road, Leeds.
 1859. Whitham, Joseph, Perseverance Iron Works, Kirkstall Road, Leeds.
 1863. Whitley, Joseph, New British Iron Works, Corngreaves, near Birmingham.
 1847. Whitworth, Joseph, Chorlton Street, Manchester.
 1852. Whytehead, William Keld, Engineer-in-Chief to the Government of Paraguay : 32 Cambridge Street, Eccleston Square, London, S.W.
 1859. Wickham, Henry Wickham, M.P., Low Moor Iron Works, near Bradford, Yorkshire.
 1859. Wickham, Lamplugh Wickham, Low Moor Iron Works, near Bradford, Yorkshire.
 1847. Williams, Richard, Patent Shaft Works, Wednesbury.
 1859. Williams, Richard Price, Stocksbridge Iron Works, Deepcar, near Sheffield.
 1856. Wilson, Edward, Great Western Railway, Worcester.
 1859. Wilson, George, Cyclops Steel and Iron Works, Sheffield.
 1863. Wilson, John Charles, East India House, 5 Lime Street, London, E.C.
 1852. Wilson, Joseph W., 9 Buckingham Street, Strand, London, W.C.
 1857. Wilson, Robert, Bridgewater Foundry, Patricroft, near Manchester.
 1860. Wilson, William, 3 Queen Square, Westminster, S.W.

1862. Winby, William Edward, Old Park Iron Works, Wednesbury.
 1859. Winter, Thomas Bradbury, 28 Moorgate Street, London, E.C.
 1863. Wise, Francis, Chandos Chambers, Buckingham Street, Adelphi, London, W.C.
 1858. Wood, Nicholas, Hetton Hall, Hetton, near Fence Houses.
 1848. Woodhouse, Henry, London and North Western Railway, Stafford.
 1851. Woodhouse, John Thomas, Midland Road, Derby.
 1861. Woodhouse, William Henry, 11 Great George Street, Westminster, S.W.
 1858. Woods, Hamilton, Messrs. Allsopp and Sons, Burton-on-Trent.
 1864. Worsdell, Thomas William, Berkley Street, Birmingham.
 1860. Worssam, Samuel William, King's Road, Chelsea, London, S.W.
 1860. Worthington, Samuel Barton, Engineer, London and North Western Railway, Manchester.
 1859. Wright, Joseph, Metropolitan Carriage and Wagon Company, Saltley Works, Birmingham.
 1860. Wright, Joseph, Neptune Forge, Tipton Green, Dudley.
 1863. Wright, Owen, Broadwell Forge, Oldbury, near Birmingham.
 1863. Wright, Peter, Railway Wheel Vice and Anchor Works, Dudley.
 1853. Wymer, Francis W., Superintending Engineer, Tyne Steam Shipping Company, 13 North Shore, Newcastle-on-Tyne.
 1861. Yule, William, Nevesky Foundry, St. Petersburg, Russia.

HONORARY MEMBERS.

1848. Branson, George, Belmont Row, Birmingham.
 1864. Branson, Joseph W., Belmont Row, Birmingham.
 1863. Brockbank, William, 37 Princess Street, Manchester.
 1863. Butler, William, 15 Bilbao Street, Cadiz, Spain.
 1851. Clare, Thomas Deykin, Carr's Lane, Birmingham.
 1848. Crosby, Samuel, Leek Street, Birmingham.
 1863. Fairbairn, John, Farnley Iron Works, Leeds.
 1863. Fisher, John, Priory Street, Dudley.
 1863. Forster, George Emmerson, Collingwood Chambers, Newcastle-on-Tyne.
 1863. Hackney, William, Richmond Cottage, New Gough Road, Edgbaston, Birmingham.
 1864. Hornblower, Joseph Wells, 14 Waterloo Street, Birmingham.
 1860. Hutchinson, William, Blue Lias Lime Stone Offices, Lyme Regis.
 1858. Lawton, Benjamin C., Benwell Grange, Newcastle-on-Tyne.
 1859. Leather, John Towler, Leventhorpe Hall, near Leeds. (*Life Member.*)
 1860. Manby, Cordy, Tower Street, Dudley.
 1863. Nichols, William, Midland Copper Works, Guild Street, Burton-on-Trent.

1864. Parsons, Charles T., Ann Street, Birmingham.
1856. Pettifor, Joseph, Midland Railway, Derby.
1864. Peyton, Abel, Oakhurst, Church Road, Edgbaston, Birmingham.
1861. Ratcliff, Charles, Wyddrington, Edgbaston, Birmingham.
1863. Rigg, Arthur, The College, Chester.
1859. Sherrieff, Alexander Clunes, Great Western Railway, Worcester.
1863. Storey, Thomas R., 17 Gracechurch Street, London, E.C.
1864. Tennant, John, St. Bollox Chemical Works, Glasgow. (*Life Member.*)
1864. Thornton, Falkland Samuel, Bradford Street, Birmingham.
1848. Warden, William Marston, Edgbaston Street, Birmingham.
1858. Waterhouse, Thomas, Claremont Place, Sheffield.
1862. Whitehead, William, Don Steel Works, Sheffield.
1863. Woolley, John, Marchay Colliery, Ripley, near Derby.

GRADUATES.

1850. Glydon, George, Spring Hill Tube and Metal Works, Eyre Street, Birmingham.
1861. Middleton, Henry Charles, Vulcan Iron Foundry, Summer Lane, Birmingham.
-

PROCEEDINGS.

28 JANUARY, 1864.

The SEVENTEENTH ANNUAL GENERAL MEETING of the Members was held at the house of the Institution, Newhall Street, Birmingham, on Thursday, 28th January, 1864 ; ROBERT NAPLIER, Esq., President, in the Chair.

The Minutes of the last General Meeting were read and confirmed. The Secretary then read the following

ANNUAL REPORT OF THE COUNCIL.

1864.

The Council have great pleasure, on this the Seventeenth Anniversary of the Institution, in congratulating the Members on the very satisfactory progress and prosperous condition of the Institution.

The Financial statement of the affairs of the Institution for the year ending 31st December, 1863, shows a balance in the Treasurer's hands of £2365 15s. 10d. after the payment of the accounts due to that date. The Finance Committee have examined and checked the receipts and payments of the Institution for the last year 1863, and report that the following balance sheet rendered by the Treasurer is correct. (*See Balance Sheet appended.*)

The Council report with great satisfaction the continued increase in the number of Members that has taken place during the past year ; the total number of Members of all classes for the year being 540, of whom 24 are Honorary Members, and 3 are Graduates, being an effective increase of 43 during the year.

The following deceases of Members of the Institution have occurred during the past year 1863 :—

WILLIAM BAGNALL,	Westbromwich.
ALEXANDER BRODIE COCHRANE,	Dudley.
JOHN FARMER,	Dudley.
JAMES FENTON,	Low Moor.
JOSHUA FIELD,	London.
BENJAMIN GIBBONS, JUN.,	Birmingham.
BENJAMIN GOODFELLOW,	Hyde.
WILLIAM WATSON HEWITSON,	Leeds.

The Council have particular pleasure in acknowledging the receipt of the handsome donation of Fifty pounds to the funds of the Institution from the President ; and also in expressing their thanks to the Donors of the valuable and acceptable additions that have been presented to the Library during the past year. The Council wish to urge on the attention of the Members the important advantage of obtaining a good collection of Engineering Books, Drawings, and Models in the Institution, for the purpose of reference by the Members personally or by correspondence ; and they trust this desirable object will be promoted by the Members generally, so that by their united aid it may be efficiently accomplished. Members are requested to present copies of their works to the Library of the Institution.

LIST OF DONATIONS TO THE LIBRARY.

- Drawing of the Engines of the Frigate "Hector," by Robert Napier and Sons ; from the President.
- Official Illustrated Catalogue of the International Exhibition of 1862 ; from the Commissioners.
- Mills and Millwork, by William Fairbairn ; from the author.
- Report on the Suez Canal, by John Hawkshaw ; from the author.
- On the Rolling of Ships, by William Froude : from the author.
- On the Change of Form of Wrought Iron in Heating and Cooling, by Lt.-Col. Clerk, R.A. ; from the author.
- On the Density of Steam, by William Fairbairn ; from the author.
- On the Expansion of Superheated Steam, by William Fairbairn ; from the author.
- On the Construction of Marine Steam Boilers, by Charles Wye Williams ; from the author.

On a new theory of the Generation of Steam, by E. J. Reed ; from Mr. C. Wye Williams.

Proceedings of the Institution of Civil Engineers ; from the Institution.

Report of the British Association for the Advancement of Science ; from the Association.

Proceedings of the Royal Institution of Great Britain ; from the Institution.

Proceedings of the French Institution of Civil Engineers ; from the Institution.

Journal of the Architect and Engineer's Society for the kingdom of Hannover ; from the Society.

Journal of the Board of Arts and Manufactures for Upper Canada ; from the Board.

Report of the United States Patent Office ; from the Commissioners.

Journal of the Royal United Service Institution ; from the Institution.

Transactions of the Institution of Engineers in Scotland ; from the Institution.

Proceedings of the South Wales Institute of Engineers ; from the Institute.

Report of the Manchester Association for the Prevention of Steam Boiler Explosions ; from the Association.

Transactions of the Royal Scottish Society of Arts ; from the Society.

Report of the Royal Cornwall Polytechnic Society ; from the Society.

Journal of the Society of Arts ; from the Society.

The Engineer ; from the Editor.

The Mechanics' Magazine ; from the Editor.

The Civil Engineer and Architect's Journal ; from the Editor.

The London Journal of Arts ; from the Editor.

The Artizan Journal ; from the Editor.

The Practical Mechanic's Journal ; from the Editor.

The Mining Journal ; from the Editor.

The Railway Record ; from the Editor.

The Steam Shipping Journal ; from the Editor.

Photograph of Locomotive for Swedish Railway ; from Mr. John Manning.

Specimens of Malleable Cast Iron ; from the President.

The Council have great satisfaction in referring to the number of Papers that have been brought before the meetings during the past year, and the practical value and interest of many of the communications and the discussions that took place upon them, which form a valuable addition to the Proceedings of the Institution. The Council request the special attention of the Members to the importance of their aid and co-operation in carrying out the objects of the Institution and maintaining its advanced position, by contributing papers on Engineering subjects that have come under

their observation, and communicating the particulars and results of executed works and practical experiments that may be serviceable and interesting to the Members; and they invite communications upon the subjects in the list appended, and other subjects advantageous to the Institution.

The following Papers have been read at the meetings during the last year:—

- On the Apparatus used for Sinking Piers for iron railway bridges in India; by Mr. Joseph F. Strong, of Allahabad.
- On a Type Composing and Distributing Machine; by Mr. William H. Mitchel, of London.
- On the Construction of Drawing Rollers for Spinning Machinery; by Mr. William Weild, of Manchester.
- On the Locomotive Engines in the International Exhibition of 1862; by Mr. Daniel K. Clark, of London.
- On the Construction of Iron Ships; by Mr. John Vernon, of Liverpool.
- On the Effects of Surface Condensers on Steam Boilers; by Mr. James Jack, of Liverpool.
- On the Mechanical Features of the Liverpool Water Works; by Mr. Thomas Duncan, of Liverpool.
- On the Mechanical Ventilation and Warming of St. George's Hall, Liverpool; by Mr. William Mackenzie, of Liverpool.
- On Machinery for the Manufacture of Plate Glass: by Mr. George H. Daglish, of St. Helen's.
- Description of the new Iron Works at Grosmont; by Mr. Hiram C. Coulthard, of Blackburn.
- Description of the Cornish Pumping Engine with Wrought Iron Beam and the Pit Work at Clay Cross Colliery; by Mr. William Howe, of Clay Cross.
- On the Processes and Mechanical appliances in the manufacture of Polished Sheet Glass; by Mr. Richard Pilkington, Jun., of St. Helen's.

The Council have much pleasure in referring to the great success and interest of the Annual Provincial Meeting of the Institution held in Liverpool last summer, and in expressing their special thanks to the Local Committee and the Honorary Local Secretary, Mr. William Stubbs, for the excellent reception that was given to the Members of the Institution on that occasion: and also to the authorities of the London and North Western Railway Company for the free special train for the excursions, and the Cunard Company

for the free special steamer for visiting the docks and other works on the river; and to the proprietors of the works that were so liberally thrown open to the inspection of the Members, for the valuable opportunity afforded to the Members for seeing their works, and for so hospitably entertaining the Members on the occasion. The Council look forward with much confidence to the important advantages arising from the continuance of these Meetings in different parts of the country, from the facilities afforded by them for the personal communication of the Members in different districts of the country, and the opportunities of visiting the important Engineering Works that are so liberally thrown open to their inspection on those occasions.

The President, Vice-Presidents, and five of the Members of the Council in rotation, will go out of office this day, according to the rules of the Institution; and the ballot will be taken at the present annual meeting for the election of the Officers and Council for the ensuing year.

SUBJECTS FOR PAPERS.

STEAM ENGINE BOILERS, particulars of construction—form and extent of heating surface—relative value of radiant surface in effect and economy—cost—consumption of fuel—evaporation of water—pressure of steam—density and heat of steam—superheated steam, simple or mixed with common steam—pressure gauges—safety valves—water gauges—explosion of boilers, and means of prevention—effects of heat on the metal of boilers, low pressure and high pressure—steel boilers—cast iron boilers—incrustation of boilers, and means of prevention—effects of surface condensers on the metal of boilers—evaporative power and economy of different kinds of fuel, coal, wood, charcoal, peat, patent coal, and coke—moveable grates, and smoke-consuming apparatus, facts to show the best plan, and results of working—plans for heating feed water—mode of feeding—circulation of water.

STEAM ENGINES—expansive force of steam, the best means of using it—power obtained by various plans—comparison of double and single cylinder engines—combined engines—compound cylinder engines—comparative advantages of direct-acting and beam engines—engines for manufacturing purposes—horizontal and vertical—condensing and non-condensing—

injection and surface condensers—air pumps—governors—valves—bearings, &c.—improved expansion gear—indicator diagrams from engines, with details of useful effect, consumption of fuel, &c.—contributions of indicator diagrams for reference in the Institution.

PUMPING ENGINES, particulars of various constructions—Cornish engines, beam engines with crank and flywheel, direct-acting engines with and without flywheel—size of steam cylinder and degree of expansion—number and size of pumps, and strokes per minute—speed of piston—pressure upon pump—effective horse power and duty—comparison of double-acting and single-acting pumping engines—construction of pumps—plunger pumps—bucket pumps—particular details of different valves—india-rubber valves, durability and results of working—diagrams of lift of valves—application of pumps—fen-draining engines—comparative advantages of scoop wheels and centrifugal pumps, lifting trough, &c.—details of pit work of pumping engines at mines.

BLAST ENGINES, best kind of engine—size of steam cylinder, strokes per minute, and horse power—details of boilers—size of blowing cylinder, and strokes per minute—pressure of blast, and means of regulation—construction of valves—improvements in blast cylinders—rotary blowing machines—indicator diagrams from air main and steam cylinder.

MARINE ENGINES, power of engines in proportion to tonnage—different constructions of engines, double cylinder engines, trunk engines—use of steam jackets—dynamical effect compared with indicator diagrams—comparative economy and durability of different boilers, tubular boilers, flat-flue boilers, &c.—brine pumps, and means of preventing deposit—salinometers—weight of machinery and boilers—kind of paddle wheels—speed obtained in British war steamers, in British merchant steamers, and in Foreign ditto, with particulars of the construction of engines with paddle wheels, &c.—screw propellers, particulars of different kinds, improvements in form and position, number of arms, material, means for unshipping, bearings, horse power applied, speed obtained, section of vessel—governors and storm governors.

ROTARY ENGINES, particulars of construction and practical application—details of results of working.

LOCOMOTIVE ENGINES, particulars of construction, details of experiments, and results of working—consumption of fuel—use of coal and wood—consumption of smoke—heating surface, length and diameter of tubes—material of tubes—experiments on size of tubes and blast pipe—construction of pistons, valve gear, expansion gear, &c.—indicator diagrams—expenses of working and repairs—means of supplying water to tenders—locomotives for steep gradients and sharp curves—distribution of weight on wheels.

AGRICULTURAL ENGINES, details of construction and results of working—duty obtained—application of machinery and steam power to agricultural

purposes—barn machinery—field implements—traction engines, particulars of performance and cost of work done.

CALORIC ENGINES—engines worked by Gas, or explosive compounds—Electromagnetic engines—particulars and results.

HYDRAULIC ENGINES, particulars of application and working—pressure of water—construction and arrangement of valves, relief valves—construction of joints—hydraulic rams.

WATER WHEELS, particulars of construction and dimensions—form and depth of buckets—head of water, velocity, percentage of power obtained—turbines, construction and practical application, power obtained, comparative effect and economy.

WIND MILLS, particulars of construction—number of sails, surface and form of sails—velocity, and power obtained—average number of days' work per annum.

CORN MILLS, particulars of improvements—power employed—application of steam power—results of working with an air blast and ring stones—crushing by rolls before grinding—advantages of regularity of motion.

SUGAR MILLS, particulars of construction and working—results of application of the hydraulic press in place of rolls—application of steam and water for extracting the last portion of saccharine matter—construction and working of evaporating pans.

OIL MILLS, facts relating to construction and working, by stampers, by screw presses, and by hydraulic presses—particulars of crushing rollers and edge stones.

COTTON MILLS, information respecting the construction and arrangement of the machinery—power employed, and application of power—cotton presses, mode of construction and working, power employed—improvements in spinning, carding, and winding machinery, &c.

CALICO-PRINTING AND BLEACHING MACHINERY, particulars of improvements.

WOOL MACHINERY, carding, combing, roving, spinning, &c.

FLAX MACHINERY, manufacture of flax and other fibrous materials, both in the natural length of staple and when cut.

ROPE-MAKING MACHINERY—hemp and wire ropes, comparative strength, durability, and cost—steel wire ropes.

SAW MILLS, particulars of construction—mode of driving—power employed—particulars of work done—best speeds for vertical and circular saws—form of saw teeth—saw mills for cutting ship timbers—veneer saws—endless band saws.

WOOD-WORKING MACHINES, morticing, planing, rounding, and surfacing—copying machinery.

GLASS MACHINERY—manufacture of plate and sheet glass—construction of heating furnaces, annealing kilns, &c.—grinding and polishing machinery.

LATHES, PLANING, BORING, DRILLING, AND SLOTTING MACHINES, &c., particulars of improvements—description of new self-acting tools—engineers' tools—files and file-cutting machinery.

ROLLING MILLS, improvements in machinery for making iron and steel—mode of applying power—use of steam hammers—piling of iron—plates—fancy sections—arrangement and speed of rolls—length of bar rolled—manufacture of rolled girders.

STEAM HAMMERS, improvements in construction and application—friction hammers—air hammers.

RIVETTING, PUNCHING, AND SHEARING MACHINES, worked by steam or hydraulic pressure—direct-acting and lever machines—comparative strength of drilled and punched plates—rivet-making machines.

STAMPING AND COINING MACHINERY, particulars of improvements, &c.

PAPER-MAKING AND PAPER-CUTTING MACHINES, new materials and results.

PRINTING MACHINES, particulars of improvements, &c.—type composing and distributing machines.

WATER PUMPS, facts relating to the best construction, means of working, and application—velocity of piston—construction, lift, and area of valves.

AIR PUMPS, facts relating to the best construction, means of working, and application—velocity of piston—construction, lift, and area of valves.

HYDRAULIC PRESSES, facts relating to the best construction, means of working, and application—economical limit of pressure.

ROTARY AND CENTRIFUGAL PUMPS, ditto ditto ditto.

FIRE ENGINES, hand and steam, ditto ditto ditto.

SLUICES AND SLUCE COCKS, worked by hand or hydraulic power, ditto.

CRANES, steam cranes, hydraulic cranes, pneumatic cranes, travelling cranes.

LIFTS for raising railway wagons—hoists for warehouses—safety apparatus.

TOOTHED WHEELS, best construction and form of teeth—results of working—power transmitted—method of moulding—strength of iron and wood teeth.

DRIVING BELTS AND STRAPS, best make and material, leather, gutta percha, vulcanised india-rubber, rope, wire, chain, &c.—comparative durability, and results of working—power communicated by certain sizes—frictional gearing, construction and driving power obtained—friction clutches—shafting and couplings.

DYNAMOMETERS, construction, application, and results of working.

DECIMAL MEASUREMENT—application of decimal system of measurement to mechanical engineering work—drawing and construction of machinery, manufactures, &c.—construction of measuring instruments, gauges, &c.

STRENGTH OF MATERIALS, facts relating to experiments, and general details of the proof of girders, &c.—girders of cast and wrought iron, particulars different constructions, and experiments on them—rolled girders—best

forms and proportions of girders for different purposes—best mixture of metal—mixtures of wrought iron with cast.

DURABILITY OF TIMBER of various kinds—best plans for seasoning and preserving timber and cordage—results of various processes—comparative durability of timber in different situations—experiments on actual strength of timber.

CORROSION OF METALS by salt and fresh water, and by the atmosphere, &c.—facts relating to corrosion, and best means of prevention—means of keeping ships' bottoms clean—galvanic action, nature, and preventives.

ALLOYS OF METALS, facts relating to different alloys.

FRICTION OF VARIOUS BODIES, facts relating to friction under ordinary circumstances—facts on increase of friction by reduction of surface in contact—friction of iron, brass, copper, tin, wood, &c.—proportion of weight to rubbing surface—best forms of journals, and construction of axleboxes—wood bearings—water axleboxes—lubrication, best materials, means of application, and results of practical trials—best plans for oil tests—friction breaks.

IRON ROOFS, particulars of construction for different purposes—durability in various climates and situations—comparative cost, weight, and durability—roofs for slips of cast iron, wrought iron, timber, &c.—best construction, form, and materials—details of large roofs, and cost.

FIRE-PROOF BUILDINGS, particulars of construction—most efficient plan—results of trials.

CHIMNEY STACKS of large size—particulars, form, mode of building, cheapest construction, etc.—force of draught, and temperature of current.

BRICKS, manufacture, durability, and strength—hollow bricks, fire bricks, and fire clay—perforated bricks, cost of manufacture, and advantages—dry clay bricks—machines for brick making—burning of bricks.

GAS WORKS, best form, size, and material for retorts—construction of retort ovens—quantity and quality of gas from different coals—oil gas, cheapest mode of making—water gas, &c.—improvements in purifiers, condensers, and gasholders—wet and dry gas meters—self-regulating meters—pressure of gas, gas exhauster—gas pipes, strength and durability, and construction of joints—proportionate diameter and length of gas mains, and velocity of the passage of gas—experiments on ditto, and on the friction of gas in mains, and loss of pressure.

WATER WORKS, facts relating to water works—application of power, and economy of working—proportionate diameter and length of pipes—experiments on the discharge of water from pipes, and friction through pipes—strength and durability of pipes, and construction of joints—penetration of frost in different climates—relative advantages of stand pipes and air vessels—water meters, construction and working.

- WELL SINKING, AND ARTESIAN WELLS**, facts relating to—boring tools, construction and mode of using.
- TUNNELLING MACHINES**, particulars of construction, and results of working.
- COFFER DAMS AND PILING**, facts relating to construction—cast iron sheet piling.
- PIERS**, fixed and floating, and pontoons, ditto ditto.
- PILE DRIVING APPARATUS**, particulars of improvements—use of steam power—particulars of working—weight of ram and height of fall, total number of blows required—vacuum piles—compressed air system—screw piles.
- DREDGING MACHINES**, particulars of improvements—application of dredging machines—power required and work done.
- DIVING BELLS AND DIVING DRESSES**, facts relating to the best construction.
- LIGHTHOUSES**, cast iron and wrought iron, ditto ditto.
- SHIPS**, iron and wood—details of construction—lines, tonnage, cost per ton—water ballast—steel masts and yards, and wire rope rigging—comparative strength and advantage of iron and wood ships.
- MINING OPERATIONS**, facts relating to mining—modes of working and proportionate yield—means of ventilating mines—use of ventilating machinery—safety lamps—lighting mines by gas—drainage of mines—sinking pits—mode of raising materials—safety guides—winding machinery—underground conveyance—stone breaking machines—mode of breaking, pulverising, and sifting various descriptions of ores.
- BLASTING**, facts relating to blasting under water, and blasting generally—use of gun-cotton, &c.—effects produced by large and small charges of powder—arrangement of charges.
- BLAST FURNACES**—shape and size—consumption of fuel—burden, make, and quality of metal—pressure of blast—horse power required—economy of working—improvements in manufacture of iron—comparative results of hot and cold blast—increased temperature of blast—construction and working of hot blast ovens—pyrometers—construction of tuyeres—means and results of application of waste gas from close-topped and open-topped furnaces—preparation of materials for furnace and mode of charging.
- PUDDLING FURNACES**, best forms and construction—worked with coal, charcoal, &c.—application of machinery to puddling.
- HEATING FURNACES**, best construction—consumption of fuel, and heat obtained.
- CONVERTING FURNACES**, construction of furnaces—manufacture of steel—casehardening, &c.—converting materials employed.
- SMITHS' FORGES**, best construction—size and material—power of blast—hot blast, &c.—construction of tuyeres.
- SMITHS' FANS AND FANS** generally, best construction, form of blades, &c.—facts relating to power employed and percentage of effect produced—pressure and quantity of air discharged—size and construction of air mains—mechanical ventilation and warming of public buildings.

COKE AND CHARCOAL, particulars of the best mode of making, and construction of ovens, &c.—open coking, mixtures of coal slack and other materials—evaporative power of different varieties.

RAILWAYS, construction of permanent way—section of rails, and mode of manufacture—mode of testing rails—experiments on rails, deflection, deterioration, and comparative durability—material and form of sleepers, size, and distances—improvements in chairs, keys, and joint fastenings—permanent way for hot climates.

SWITCHES AND CROSSINGS, particulars of improvements, and results of working.

TURNTABLES, particulars of various constructions and improvements—engine turntables.

SIGNALS for stations and trains, and self-acting signals.

ELECTRIC TELEGRAPHS, improvements in construction and insulation—coating of wires—underground and submarine cables—mode of laying.

RAILWAY CARRIAGES AND WAGONS, details of construction—proportion of dead weight.

BREAKS for carriages and wagons, best construction—self-acting breaks—continuous breaks.

BUFFERS for carriages, &c., and station buffers—different constructions and materials.

COUPLINGS for carriages and wagons—safety couplings.

SPRINGS for carriages, &c.—buffing, bearing, and draw springs—range, and deflection per ton—particulars of different constructions and materials, and results of working.

RAILWAY WHEELS, wrought iron, cast iron, and wood—particulars of different constructions, and results of working—comparative expense and durability—wrought iron and steel tyres, comparative economy and results of working—mode of fixing tyres—manufacture of solid wrought iron wheels.

RAILWAY AXLES, best description, form, material, and mode of manufacture.

The Papers are to be written in the third person, on foolscap paper, on one side only of each page, leaving a clear margin of an inch width on the left side. In the subjects of the papers, extracts from printed publications and questions of patent right or priority of invention are not admissible.

The Diagrams to be on a large scale and strongly coloured, so as to be clearly visible to the meeting at the time of reading the paper. Enlarged details to be added for the illustration of any particular portions, drawn full size or magnified, with the different parts strongly coloured in distinctive colours. Several explanatory diagrams drawn roughly to a large scale in dark pencil lines and strongly coloured are preferable to a few small-scale finished drawings. The scale of each diagram to be marked upon it.

INSTITUTION OF MECHANICAL ENGINEERS.

WALTER MAY,

28th January, 1864.

MEMOIRS

OF MEMBERS DECEASED IN 1863.

WILLIAM BAGNALL was born at Darlaston, Staffordshire, on 4th April 1797, and at an early age entered the ironworks of his father, who was a coal and iron master at Westbromwich and Tipton: he became a partner in the works in 1828, together with four of his brothers, and took an active part in the practical management. In 1840 by the death of his elder brother he became the senior member of the firm of Messrs. John Bagnall and Sons, having extensive ironworks and collieries in South Staffordshire, the quality of the iron manufactured being known as the IB Crown brand: he also took great interest in the extensive schools established in connection with their works for the workpeople and their families. This position he continued to hold until his death, which occurred suddenly, after only a few hours' illness, at his residence at Handsworth near Birmingham, on 12th August 1863, at the age of sixty-six. He was elected a Member of the Institution in 1848.

ALEXANDER BRODIE COCHRANE was born at Dudley on 10th February 1813, and at the age of seventeen was engaged at Messrs. Grazebrook's collieries and ironworks near Dudley, which were then under the management of his father. In 1838 he started a small ironfoundry at Bilston in conjunction with Mr. John Joseph Bramah; and in 1840, in conjunction with his father and Mr. Bramah, commenced the Woodside Iron Works near Dudley. Upon the death of Mr. Bramah the late Mr. Charles Geach became his partner, and afterwards also the late Mr. Archibald Slate; and he subsequently carried on these

works in conjunction with his brother and son. Amongst the public works there executed were the castings for the Exhibition building of 1851, the Copenhagen gas and water works, the pipes for the Melbourne water works, the large caisson and dock gates for the Victoria docks, London, and several large iron bridges, including Westminster Bridge, the Charing Cross Railway bridges, and the Rochester road bridge and swing bridge. In 1853 Mr. Cochrane also entered upon large undertakings in the North of England, including collieries in Northumberland and Durham, and the Ormesby Iron Works at Middlesborough. He continued in the active management of these numerous concerns until prevented by serious ill health some years before his death. At the Woodside works he carried out successfully the application of coking in ovens to the Staffordshire slack, and read a paper before the Institution in May 1861 upon the nature of the process and the results obtained. He became a Member of the Institution in 1847, the year of its commencement, and was for some years before his death a Vice-President of the Institution. His death took place on 23rd June 1863, after a long and severe illness, at his residence, Stourbridge, in the fifty-first year of his age.

JOHN FARMER was born on 22nd January 1796 at Kingswinford near Dudley, and his first situation was at Messrs. Heywood's ironworks at Brockmoor; from whence, on the opening of the Shut End Iron Works by Messrs. Bradley and Co. in 1816, he was appointed manager of these works, and retained that position to the time of his death, which took place on 22nd August 1863, in the sixty-eighth year of his age. He was elected a Member of the Institution in 1862.

JAMES FENTON was born at Dunkenny in Forfarshire on 29th August 1815; and after leaving the Glasgow University was apprenticed as a mechanical engineer to Messrs. James Cook and Co. of Glasgow, and afterwards as a civil engineer to Mr. Blackadder of Glamis. His first appointment was under Mr. Brunel on the Great Western Railway at its formation in June 1837; after which he was

appointed resident engineer and locomotive superintendent on the Manchester and Leeds Railway in 1841. In 1845 he became acting engineer of the Leeds and Thirsk Railway, for which the bill had just been obtained; but previous to the completion of the line he undertook in 1846 the management of the Railway Foundry, Leeds, where the well-known "Jenny Lind" class of locomotive engines were built from his designs: a class of engine which, on account of its simplicity of construction combined with its steadiness at a high speed, was extensively adopted for passenger engines. He also constructed and launched the large landing stage at New Holland for the steamboat ferry across the Humber to Hull. In 1851 he was appointed consulting engineer to the Low Moor Iron Company, a position which he retained to his death. He was elected a Member of the Institution in 1847, the year of its commencement, and took a very active part in promoting its interests; he was elected a Vice-President of the Institution in 1857 and re-elected in each year subsequent. He died on 22nd April 1863, in the forty-eighth year of his age, at Leamington, where he had for some time resided for the benefit of his health.

JOSHUA FIELD was born at Hackney in 1786, his father being an extensive corn merchant. After leaving school in 1802 he spent two years in the machinery department of Portsmouth dockyard, then recently commenced under the superintendence of General Sir Samuel Bentham, and afterwards a year in the Admiralty drawing office at Whitehall. He was then engaged by Mr. Maudslay as draughtsman upon the block machinery invented by the elder Brunel, which was then in course of construction by Mr. Maudslay, with whom he was thus brought into connection, and with whom he thenceforward continued, being first in the original factory in Margaret Street, Cavendish Square, which was removed in 1810 to the present site at Lambeth, where he became a partner in 1822. Steam navigation having been introduced about 1812, he was principally engaged in the manufacture of marine engines, first for paddle-wheel vessels and more recently for the large screw war steamers. His name is specially connected with the introduction of

steam navigation, and with bringing to its present state of perfection the Marine Engine, in the improvement of which he took a very active part, from the early 10-horse power engines of the "Richmond" and "Regent" made in 1815, to the large horizontal screw engines of 1350 nominal horse power made by his firm in 1862 for the iron-plated frigate "Agincourt." He became a Member of the Institution in 1862, and died on 11th August 1863, at the age of seventy-six.

BENJAMIN GIBBONS, JUN., was born on 20th May 1815 at Redland near Bristol, and was the youngest son of the late William Gibbons, who was largely connected with the iron and shipping interests of that port. He commenced business in the South Staffordshire iron district about 1840 by developing some of the fire-clay mines at Sedgley, and about 1844 began making the cinder pig iron for foundry purposes at the Corbyn's Hall Furnaces near Dudley, and afterwards continued to do so at the Millfield Furnaces. He subsequently carried on also many successful mining operations both in Staffordshire and Derbyshire, and in 1856 established the Soudley Furnaces in the Forest of Dean, where he made the Soudley brand of pigs. He was elected a Member of the Institution in 1860; and died at his residence, Birmingham, on 3rd September 1863, at the age of forty-eight, from the results of a slight accident.

BENJAMIN GOODFELLOW was born in 1811 at Rainow near Macclesfield, and began to work in a silk mill at the age of six years: on the removal of his parents to Hyde near Manchester, he worked at the Carrfield Mills, Floweryfield, until 1838, and was ultimately employed there as a mechanic upon the various machines used in spinning and weaving cotton. About two years later he established works of his own, for the manufacture of the steam-engine piston known by his name, and for general engineering work; being particularly successful in his arrangements of compound steam engines for economising fuel, which have been largely adopted in the cotton manufacturing districts. He was one of the original

Members of the Institution from its commencement in 1847 ; and died on 29th April 1863, in the fifty-second year of his age.

WILLIAM WATSON HEWITSON was born at Newcastle-on-Tyne in 1815 ; and after serving his time at Messrs. Robert Stephenson and Co.'s works in that town he was for some time in the locomotive shops of Messrs. Fenton Murray and Jackson at Leeds. From thence he went to the locomotive works of Messrs. Kitson and Co. at Leeds, taking the position of manager and principal draughtsman ; and in 1842 he became a member of that firm, and continued so until his death on 7th May 1863, at the age of forty-eight. He had made the locomotive engine his special study from his first connection with business ; and during the last two years of his life rendered material assistance in the development of the system of steam ploughing, in connection with Mr. John Fowler. He was a Member of the Institution from 1848.

The CHAIRMAN congratulated the Members upon the growing prosperity of the Institution and the very satisfactory progress it had made in the number of Members and increase of funds, and in the value and interest of the papers communicated: he moved that the Report of the Council be received and adopted, which was passed.

The CHAIRMAN announced that the Ballot Lists had been opened by the Committee appointed for the purpose, and the following Officers and Members of Council were found to be duly elected for the ensuing year:—

PRESIDENT.

ROBERT NAPIER, . . . Glasgow.

PAST-PRESIDENTS.

Ex-officio permanent Members of Council.

SIR WILLIAM G. ARMSTRONG, . Newcastle-on-Tyne.

JAMES KENNEDY, . . . Liverpool.

JOHN PENN, . . . London.

JOSEPH WHITWORTH, . . Manchester.

VICE-PRESIDENTS.

CHARLES F. BEYER, . . . Manchester.

EDWARD A. COWPER, . . London.

ROBERT HAWTHORN, . . Newcastle-on-Tyne.

SAMPSON LLOYD, . . . Wednesbury.

HENRY MAUDSLAY, . . . London.

JOHN RAMSBOTTOM, . . Crewe.

COUNCIL.

ALEXANDER ALLAN, . . . Perth.

JOHN ANDERSON, . . . Woolwich.

FREDERICK J. BRAMWELL, . London.

CHARLES COCHRANE, . . Dudley.

WALTER MAY, . . . Birmingham.

C. WILLIAM SIEMENS, . . London.

Members of Council remaining in office.

DANIEL K. CLARK, . . .	London.
WILLIAM CLAY, . . .	Liverpool.
JOHN FERNIE, . . .	Leeds.
SIR CHARLES FOX, . . .	London.
GEORGE HARRISON, . . .	London.
THOMAS HAWKSLEY, . . .	London.
EDWARD HUMPHRYS, . . .	London.
EDWARD JONES, . . .	Wednesbury.
CHARLES P. STEWART, . . .	Manchester.

TREASURER.

HENRY EDMUNDS, . . .	Birmingham.
----------------------	-------------

SECRETARY.

WILLIAM P. MARSHALL, . . .	Birmingham.
----------------------------	-------------

The following New Members were also elected :—

MEMBERS.

DAVID CAMPBELL, . . .	Liverpool.
WILLIAM THOMAS CARRINGTON, . . .	London.
GEORGE HEATON DAGLISH, . . .	St. Helen's.
CHARLES E. DARBY, . . .	Wrexham.
EDWARD HENRY FOSTER, . . .	Wednesbury.
ELIOT HOWARD, . . .	London.

The following paper was then read :—

DESCRIPTION OF A MACHINE FOR BREAKING LIMESTONE AND ORE AT KIRKLESS HALL IRON WORKS.

BY MR. JOHN LANCASTER, OF KIRKLESS HALL, WIGAN.

This Stone Breaking Machine, which is the invention of Mr. Blake of Newhaven, Connecticut, is employed for breaking limestone and ore for blast furnaces and also stone for metalling roads. It is driven by steam power, and consists of a crushing hopper, in which the stone is broken between a pair of jaws, one fixed in the frame of the machine, and the other vibrating on a centre through a short distance, worked by an ordinary toggle joint and long lever which receives its motion from a crank shaft.

The machine is shown in Figs. 1, 2, and 3, Plates 1 to 3; Fig. 1 is a longitudinal section, Fig. 2 a plan, and Fig. 3 an end elevation.

The fixed jaw A, Fig. 1, Plate 1, against which the stone is crushed, is a vertical fluted block of cast iron, bedded in zinc in the end of the very strong cast iron frame of the machine, and held in its place by loose tapered cheek pieces BB, as seen in the plan, Fig. 2, which fit into recesses on each side of the hopper. The moveable jaw C is fluted on the breaking face to correspond with the fixed jaw, the ridges of the moveable jaw being opposite the grooves of the fixed jaw: and the moveable jaw is suspended from a large transverse pin above the frame. At the back of the moveable jaw to give the motion are two struts D D, in the form of flat cast iron plates extending the whole width of the jaw and bearing in the middle in the upright thrust bar E; this bears at the bottom upon the main lever F, the whole forming a horizontal toggle joint of simple construction and great strength. Figs. 4 and 5, Plate 3, show the thrust bar E of the toggle joint;

and Fig. 6 is a plan of one of the strut plates D. The main lever F, Fig. 1, has its fulcrum on a cross beam cast in the frame of the machine, and when lifted by the connecting rod and crank G at the outer end it presses forward the breaking jaw C by straightening the toggle joint. In the depression of the lever the jaw is drawn back ready for the next stroke by the india-rubber spring I.

The entire frame of the machine is in one single casting, and has feet cast upon it to stand upon a brick or stone foundation: the feet have bolt holes cast in them for the purpose of bolting the machine down to the foundation; in practice however it is found to require nothing besides its own weight, about 8 tons, to keep it steady in its place. It is fixed high enough to allow a railway wagon or a cart to be placed under the hopper to receive the broken material direct from the crushing jaws. The crank shaft G carries a flywheel H on each side of the machine, and also the driving pulley K, which receives a belt from the steam engine or shafting employed to drive the machine.

The moveable jaw C, Fig. 1, Plate 1, works on a round bar of iron, which passes loosely through it and forms the centre upon which it vibrates. Every revolution of the crank causes the lower end of the moveable jaw to advance towards the fixed jaw about $\frac{3}{8}$ inch and return; and when the jaw is drawn back the stone in the hopper falls lower down to fill up the space caused by drawing back the jaw, and is then ready for the next bite of the jaws, and so on until the broken stone drops out at the bottom. The extent of motion of the crank end of the main lever F is $5\frac{1}{2}$ inches, giving a total leverage of 14 to 1. The distance of the jaws apart at the bottom determines the size of the broken material, and can be altered at pleasure. A variation of $\frac{5}{8}$ inch can be made by raising or lowering the screws which adjust the wedges L, thereby altering the abutment for the toggle joint. Further variations are made by changing the strut plates D, and putting in longer or shorter ones as may be required.

The writer first became acquainted with this stone breaking machine at the International Exhibition of 1862, where a working model of it was shown in action; and from its simplicity and the

ease with which the model broke hard flint stones he was induced to obtain a machine from the inventor in America for the purpose of breaking iron ore and limestone at the Kirkless Hall Iron Works, Wigan. This machine was started in October 1862, and since that time has worked continuously. The size of the jaws is 20 inches long by 7 inches width of opening at the top; and this therefore represents the largest stone which the machine will break. The largest quantity of limestone broken in one day of 10 hours has been 120 tons, or at the rate of 12 tons per hour; but the average weight turned out in regular work is 100 tons per day, or 10 tons per hour.

In consequence of the economy and advantage found in using this machine as compared with hand labour, a second machine was procured by the writer from the English maker, Mr. Marsden of Leeds, which was started in August last. This was intended solely for limestone, having the jaws 20 inches long by 10 inches width of opening at the top, so as to enable a large stone to be thrown direct into the jaws without having to be broken previously by a hammer. This second machine is found to break about the same quantity of stone per day as the first one. The first machine is now used for reducing the size of any iron ore or other material which may require to be broken small for the blast furnaces; as well as for breaking furnace slag for road making.

From the experience obtained with the two machines the writer has found that the cost of breaking any material to about the size of road metal is 3*d.* per ton. This includes unloading the material out of wagons, and feeding it into the machine, together with the engine power and all expenses connected with the machine. The speed of the machine it is found should not be less than 200 strokes per minute. When the jaws are fixed as close as they can be, namely about 1 inch apart at the bottom, the yield is about 5 tons per hour; but when they are $1\frac{1}{2}$ to $1\frac{3}{4}$ inch apart at the bottom, the quantity already named of 10 to 12 tons per hour can be got through. The indicated horse power required to drive one machine of the largest size is 15 horse power.

The only parts of the machines at the writer's works which have been replaced up to the present time are the fixed and moveable jaws; these with constant work last about six months. It has been found that none but white or mottled iron with the fluted faces well chilled will stand the severe rubbing and crushing action which takes place. This is all the wear that is experienced in the working parts, except the ordinary wear of the brasses of the connecting rod and crank shaft. Fig. 7, Plate 4, shows a section of the jaws to a larger scale; and Figs. 8 and 9 are full size sections showing the different forms of teeth with which the jaws are made.

The special points of advantage found in this machine are its strength of construction, and small amount of wear and tear, in consequence of the parts that are subjected to the severe strain required for crushing stone being simple pressure pieces of cast iron, of an advantageous form for strength, and having large bearing surfaces and small extent of motion on the bearing surfaces. Also the only parts exposed to wear by the stone whilst being crushed are the two jaws, which are plain solid castings of $14\frac{1}{2}$ and $5\frac{1}{2}$ cwt. weight, without any fitting upon them, and readily taken out and renewed.

A working model of the stone breaking machine was shown in action, readily breaking up pieces of the hardest flint, limestone, and ironstone.

The CHAIRMAN remarked that the cost named in the paper of 3*d.* per ton for breaking stone and ore by the machine appeared very low, amounting to only 25*s.* for the average production that had been stated of 100 tons per day: and he enquired whether that covered the whole expense of working, including breaking and carting away.

Mr. LANCASTER replied that the cost of 3*l.* per ton did not include carting the stone away, but covered all the other expenses of breaking.

Mr. E. A. COWPER enquired what was the cost of coal at the Kirkless Hall Works: the cost of 3*l.* per ton for breaking limestone and ore certainly appeared very low, if that included steam power, coals, and attendance, for working the machine which required 15 horse power to drive it.

Mr. LANCASTER said all those expenses were covered by the cost of 3*l.* per ton, and the cost of coal at his works was 3*s.* 6*d.* per ton.

The CHAIRMAN enquired whether the machine was found to work slower with one kind of material than with another.

Mr. LANCASTER replied that the iron ore at the Kirkless Hall Works was of a very hard quality and therefore worked rather slower in the machine than other ores, requiring a great deal of crushing to reduce it: but generally it was found that heavier materials passed through the machine quicker than lighter ones, their greater weight keeping them well down between the jaws of the machine.

The CHAIRMAN enquired whether the working model now exhibited of the machine was the same that was shown in the International Exhibition of 1862.

Mr. MARSDEN replied that the present model was similar to the one shown in the Exhibition, and was made at the same time, about five years ago, when he made several models of the machine for the purpose of introducing it into England and other countries. Even the small model now shown was powerful enough to break raw uncalcined flints quite easily, as was now seen; by setting the flywheel revolving with only a moderate start by the handle, the flints were broken into small bits immediately on dropping them into the jaws: whereas in any ordinary mill for grinding or crushing materials, if a flint stone got in it would stop the motion of the machine or break some part of it. When the present machine was used for breaking raw flints, it was necessary to keep the hopper covered, to prevent the pieces from flying out, unless the stone was fed in by a cartload at a time, so as to keep the hopper always full.

The CHAIRMAN asked whether the machine had been tried for breaking granite for macadamising roads.

Mr. MARSDEN replied there were about fifty of the machines now in use at granite quarries, breaking the granite chips for making roads, where the chips would otherwise be wasted or would have to be broken by hand labour at a cost of 2s. per ton. This was now done by the machine at the cost of 3*l.* per ton, and the broken stone was produced as fast as the carts could take it away. Many of the machines were also employed for crushing emery stone for grinding, in which a great saving was effected by their use, as they did not make anything like so much flour as the ordinary grinding machines. Hitherto it had been difficult to breathe in an emery mill, owing to the quantity of fine flour with which the air was impregnated; and the emery flour was the least valuable sort of emery, being the waste of the mill, as it was impossible to grind the emery down to any size of grain without also making the flour. The new machine however crushed the emery into the smallest pieces required for the grinding mill, with only a very small quantity of flour.

The CHAIRMAN enquired what was the size to which the emery was reduced by the crushing machine.

Mr. MARSDEN replied that the great expense and waste in emery mills was in reducing the large lumps of emery stone into pieces of the size suitable for the grinding mill, about the size of marbles, which could then be speedily ground to grain. The smallest machine he made, weighing about $3\frac{1}{2}$ tons, broke the lumps into pieces rather smaller than marbles, as small as the bits produced by the working model now exhibited. The machine was also used for crushing tin, copper, or gold ores, and was found to have advantages over the ordinary stamps employed for the purpose; for in stamping these ores the stamps knocked all the matrix into a pulverised mass, and the practice was for this whole mass of material to be taken from the stamps to the washing apparatus, to remove the foreign matters mixed with it. But with the new machine 75 per cent. of the foreign matter crushed could be picked out at once, by having a revolving table under the machine with boys standing round it to

pick the large pieces of stone off, leaving only 25 per cent. to be washed, instead of the whole mass; since the action of the machine was to open the seams and let the true metal go without pulverising.

The CHAIRMAN asked what was the cost of the machines.

Mr. MARSDEN replied that the cost of the largest machine, having the jaws 20 inches long by 10 inches width of opening at top, was £240 complete. The smallest machine on this construction, weighing $3\frac{1}{2}$ tons, cost £140, and had been made in the United States before the machine was introduced into England; it was now at work at a whinstone quarry at Witton-le-Wear, breaking 40 tons per day of whinstone, and he had seen it break as much as $3\frac{1}{2}$ to 4 cubic yards per hour. The largest machine he had made in America had the jaws 20 inches long by only 7 inches wide, instead of 10 inches width of opening as now made.

The CHAIRMAN enquired for what purpose the machine was employed in the first instance in America, and whether many breakages of the cast iron frame occurred before the proper strength was arrived at.

Mr. MARSDEN said he had had several breakages before the cast iron frame was made strong enough to stand the severe strain thrown upon it in crushing stone. The work upon which the machine was first employed in America was breaking stones in the central park in New York, in which there were from 5 to 7 miles of road to be made in 1858. A great quantity of stone was therefore required to be broken for these roads, and none was allowed to be laid on the road which would not pass through a ring of 2 inches diameter: the price paid for breaking the stone by hand labour was nearly 10s. per cubic yard. The first machine made was taken to the park, and broke the stone on contract for only 3s. per cubic yard, and at the end of the first three months it had earned enough by the saving at that rate to pay its entire cost, while at the same time the work was found to be done much better by the machine than it had previously been done by hand labour at more than three times the cost. The stones to be broken were boulders of hard blue trap rock, as hard as flint and considerably tougher, and the strain put

upon the machine to break them was greater than anything that had been met with in breaking any other materials. By the action of the jaws of the machine indeed the hardest substances were gradually broken up into pieces, and in two instances hammer heads that had accidentally fallen into the jaws had been crushed to pieces. One of these accidents occurred with the machine at work in New York, while he was standing close to it; the hammer was used for knocking the stones down in the jaws of the machine if they were too large to enter, and the head got loose and came off the wood handle and fell into the jaws. It was a cast steel head weighing 28 lbs., and was crushed to pieces by the machine, which was enabled to effect this by the circumstance that the divergence of the jaws was sufficient to allow any very hard substance that got between them to slip up when the excessive pressure of the jaws in closing came upon it; but then, when the jaws opened again, it again fell down lower between them, a small portion being chipped off each time, and in that way by a continued nibbling action the hardest material was gradually broken small enough to fall through. The second hammer head that was destroyed in that manner was in the machine described in the paper at the Kirkless Hall Works; and he had recently seen another there also, which had fallen into the machine and showed the marks of the jaws upon it, but had been picked out before being crushed to pieces.

Mr. J. C. WILSON enquired what was the inclination of the jaws of the machine to each other.

Mr. MARSDEN replied that he had tried different inclinations of the jaws, and the moveable jaw was now placed at the inclination shown in the drawing, the fixed jaw being upright. The jaws were from 7 to 10 inches wide at the top and 2 inches or less at bottom, with a depth of from 18 to 24 inches from top to bottom, the inclination being kept in all cases the same.

Mr. J. C. WILSON enquired whether the machine would be suitable for granulating animal charcoal; the machinery at present in use for that purpose was very expensive.

Mr. MARSDEN thought if the charcoal were dry the machine would quickly break it up to any degree of fineness required.

The CHAIRMAN asked what was the make of the suspending pin on which the moveable jaw worked.

Mr. MARSDEN replied it was only a piece of common round rolled iron, not turned and with only sufficient dressing to prevent its being too rough for the jaw to work upon ; the ends were flattened and keyed fast in the frame of the machine.

Mr. WILSON LLOYD enquired whether the cost of 3*d.* per ton which had been stated for breaking limestone at the Kirkless Hall Works included any charge for interest on the capital expended in the machine. That would affect the question as to the probability of this machine superseding hand labour for the purpose.

Mr. LANCASTER said the cost of 3*d.* per ton did not include any charge for interest on capital or depreciation. It was merely the contract price for lifting the stone into the machine, putting the wagons under, and working the machine in the usual way ; and that was the average cost for crushing ordinary materials.

Mr. WILSON LLOYD did not see, that being the case, how a saving could be effected by the machine as compared with hand labour, because at their own works at Wednesbury limestone was broken by hand labour at a cost of only 3½*d.* per ton ; and if a charge for interest on capital and depreciation were added to the cost of 3*d.* per ton in breaking limestone by the machine, that would bring up the cost to considerably above 3*d.* per ton. A great improvement for reducing the expense with the machine would be effected if it were made self-feeding : at present it appeared that every lump of material to be crushed had to be lifted by hand from the ground and thrown into the jaws of the machine ; but if it were fed direct from the wagons by means of an inclined plane, the cost of working would be materially lessened.

Mr. LANCASTER had not found he could get limestone broken by hand labour for so little as 3½*d.* per ton at his works, and the cost by hand labour had been as much as 7*d.* per ton, in comparison with which the present cost of 3*d.* per ton with the machine was a great saving. The machine had also the important advantage of breaking the materials to a much more uniform size than could be done by hand labour, and uniformity in the size of the pieces suited

the working of the blast furnace better than irregular lumps. Moreover with hand labour it was found that often in the night time the men in charge of the furnaces threw in lumps both of ore and limestone which were much too large, and interfered with the regular working of the furnace and the proper make of iron: but this could not be done when the machine was used, as the materials were constantly crushed by it to a uniform size. He enquired what was the size of the pieces that were broken by hand labour at the cost of $3\frac{1}{4}d.$ per ton.

Mr. WILSON LLOYD said the limestone was broken by hand labour to pieces about 3 inches cube. As labour was growing very costly in South Staffordshire a machine for crushing limestone cheaply was a great desideratum; but he had expected to find the cost of breaking stone by the machine would probably be only about half as much as appeared to be actually the case.

Mr. LANCASTER observed that the larger size of the pieces broken by hand labour would make a great difference in the expense of breaking; for the cost of breaking stone by hand labour to so small a size as $1\frac{1}{2}$ inch was many times greater than in reducing it to 3 inches only.

Mr. E. A. COWPER thought the application of the machine to breaking the materials for blast furnaces was decidedly a step in the right direction, as it was very important to have the materials broken fine for the purpose; and the more intimately the ore and limestone were mixed in the furnace, the better would be the yield of iron and the more economical its production.

Mr. SAMUEL LLOYD enquired whether more dust was made in breaking limestone and ore by the machine than by hand labour, as the introduction of dust into a blast furnace was not advantageous: with hand labour he had found very little dust was left after breaking large quantities of material.

Mr. LANCASTER replied that practically no dust was made by the machine, and the whole of the broken material was taken direct from the machine to the furnace without riddling or screening.

Mr. MARSDEN said he had tested the machine during the last five years, in reference to the quantity of dust that it made; and had

found that in breaking hard material, such as hard limestone, the dust made by the machine was only about two-thirds as much as that made in hand breaking. The machine was intended for breaking materials that were too hard to be suitable for breaking by hand and would cost too much if broken sufficiently small by hand; but softer stone might still be broken by hand at a cheap rate. In road making, the size of the stones laid down was of great importance to the durability and usefulness of the road: at present a newly macadamised road was not fit for some time for horses or vehicles to pass over, and by the time it became ready for use it was already half worn out, and in holes in some places; but if the stones were broken small enough to go through a $1\frac{1}{2}$ inch ring, and then the chippings laid on the top of these, a compact road would be obtained ready for immediate use. By hand labour however it was of course impossible to get the stone broken so small as that, on account of the great expense, as breaking down stones to $1\frac{1}{2}$ inch size was double the work of breaking them down to 2 inches size; and here therefore the machine had a decided superiority.

The CHAIRMAN enquired how many of the machines were now at work in England.

Mr. MARSDEN replied that there were now about fifty of the machines at work in this country, several of which were being employed to break stones for macadamising roads; some of these were in country districts where there was an agricultural engine at hand, which would otherwise be standing idle for a great part of the year. The machines were always made self-feeding wherever practicable, either by a slanting shoot when the stone was at a higher level, or by elevators to raise it from below into the jaws of the machine. One of the machines at a quarry had been fixed on the side of the hill, with an inclined shoot for the stones to pass direct into the machine, and by that mode of feeding one man could feed 100 tons of stone per day into the machine, thus doing what would be the work of four men if the stone were fed in by hand. With the addition of a tramway to bring up the wagons immediately under the machine, he had seen a train of twelve wagons loaded in twenty minutes, by merely lifting a trap door of the bin and letting

the broken stone run into the wagons. And when the stone was quarried in the side of a hill and passed by a shoot direct into the jaws of the machine and thence into the wagons beneath, it was found that it could be broken and delivered fifty miles away by rail at less expense than it had formerly cost for loading and delivering the rough stone. Where the stone had to be lifted by hand into the jaws of the machine it generally cost an additional 1*7*. per ton. The machine at the Kirkless Hall Works was placed at a level part of the works, so that there was no facility in that case for making it self-feeding, as it could not be placed below the level of the materials to be crushed. All the stone had therefore to be lifted into the jaws by hand, and he had known as much as 30 tons per day thrown in by one man, at a cost of 2*s*. 6*d*. in that instance. That was the first machine put to work in England, and all the machines now in use in this country had been introduced since 1862.

Mr. J. RAMSBOTTOM had seen the machine at work at the Kirkless Hall Works on the occasion of the Liverpool Meeting of the Institution last August, and was much struck with the simplicity of its construction and its low cost, and its excellent action in breaking the limestone and ore for the blast furnaces. He thought the machine might be applied with advantage to breaking stones for ballast for the permanent way of railways, where it would be a great improvement to have the ballast of uniform quality throughout, so as to form an even and durable road.

Mr. E. A. COWPER had also seen the machine at work in the North of England, employed in breaking blast-furnace cinder for making roads, in which it appeared very effective, though seeming to make rather too much dust in the process. With regard to the utility of breaking stones small for macadamising, he thought 2 inch stones were not too large for the purpose if a heavy roller were passed over the road, supposing the road had been softened by water or recently picked up. The effect of passing a roller over was to bring the flat sides of the triangular or pyramidal pieces of stone uppermost, and he had seen a macadamised road made in that way in beautiful condition after a heavy roller had been twice passed over it; the rolling of a road was thus a matter of great importance as a measure of economy, for it saved the great waste caused by the

stones rolling about and being gradually ground away before they settled or became imbedded in the road. In the working of the machine he had occasionally seen hard stones become jammed, but they always gave way gradually under the constant crushing action of the machine, and were finally crushed to pieces without having strained or damaged the machine. This was readily explained by the consideration that the action of the jaws upon a substance too hard for them to crush entirely through was to crumble away the edges of the substance immediately in contact with the jaws, and then the broken particles reduced the friction between the surfaces and acted to some extent as a lubricator, allowing the hard substance to slip upwards in the jaws and relieve the pressure: and by this continual biting action he could understand how any substance which was not actually harder than the surface of the chilled cast iron jaws themselves might be gradually crumbled away and at last broken up.

Mr. MARSDEN remarked that there was a difference in the make of the jaws in the machines intended for breaking stones for roads, where it was desirable to avoid making dust, and in those used for crushing "bulldog" for lining puddling furnaces, where it did not matter making dust. For the latter purpose the teeth of the jaws were made flatter, the depth of the corrugations being only about $\frac{1}{2}$ inch, Fig. 8, Plate 4: whereas in the machines intended for breaking stones for roads the corrugations were made sharper, Fig. 9, projecting $\frac{3}{4}$ inch instead of $\frac{1}{2}$ inch, the teeth being spaced at the same pitch apart in both cases, $2\frac{1}{2}$ inches centre to centre. The point of the teeth was made flat for $\frac{1}{8}$ to $\frac{1}{4}$ inch breadth, with the edges just rounded off. One of the machines with the sharper teeth was now employed at a chemical works at Gateshead for crushing pyrites, where it was desired to make the least dust possible, and it had proved highly satisfactory for this purpose; other modes of crushing the material had previously been tried there, but they had all been found expensive and made a great deal of dust.

The CHAIRMAN moved a vote of thanks to Mr. Lancaster for his paper, which was passed.

The following paper was then read:—

DESCRIPTION OF A HORIZONTAL V PUMP.

BY MR. JOHN J. BIRCKEL, OF LIVERPOOL.

The Pump forming the subject of the present paper is shown in Figs. 1, 2, and 3, Plates 5 and 6, which represent a double pump of this kind as constructed at the Vauxhall Foundry, Liverpool. In this pump the barrel is horizontal and moves upon a stationary bucket, instead of the bucket moving within a stationary barrel as in an ordinary pump; and it is termed a **V** pump on account of the peculiar shape of both barrel and bucket. Fig. 1, Plate 5, is a transverse section through the two pump barrels, and Fig. 2 a longitudinal section of the pump through one of the barrels: Fig. 3, Plate 6, is a plan. Fig. 4, Plate 7, shows a longitudinal section of one of the barrels to a larger scale, and Fig. 5, Plate 8, is a corresponding transverse section.

The lower half **A** of the barrel, Figs. 1 and 2, Plate 5, acts as a stationary bed, being fixed water-tight to the foundation plate **B**; the working portions are planed true throughout their entire length, and the angle of the **V** is 90 degrees, as seen in the transverse sections, Figs. 1 and 5. The upper or sliding half **C** of the barrel is also planed true throughout its length inside, as well as upon its return flanges, which make a water-tight joint with the lower half **A**. The barrel is made complete by the two end covers **D D**, in each of which is an aperture closed by a leather flap valve **E**, Fig. 4, Plate 7; these covers are bolted on the sliding barrel **C**, and are fitted true by planed faces upon the **V** bed **A**, with which they make a water-tight joint. A handle **F**, Figs. 1 and 2, is fixed to the sliding barrel **C** for convenience of lifting it out of its seat. The stationary bucket **G**, Figs. 2 and 4, is fixed to the bed **A**, and makes a water-tight joint both with the bed **A** and with the sliding barrel **C**; it communicates by means of the central opening with the suction chamber **H**, Figs. 1 and 5, and opens at both ends

into the pump barrel, each opening being provided with a leather flap valve I, Fig. 4. The bucket is thus made to answer as the suction valvebox, whereby the pump is rendered double-acting by means of only a single valvebox.

When the sliding barrel C, Fig. 4, Plate 7, is set in motion, the water is drawn into it at one end through one of the suction valves I; while at the same time the water contained in the other end of the barrel is discharged through the delivery valve E at that end. The delivery valves E are prevented from opening too far by the catches J; and a similar provision is made with the two suction valves I, which are connected together by a chain. The pump works in a cistern K upon the foundation plate B, Figs. 1 and 2, into which it delivers the water raised; and a continuous discharge takes place through the overflow spout L, which is placed at such a height as to keep all the joints of the pump constantly immersed in the water, thus making them air-tight. When it is desired to use the pump as a force pump, it is only necessary to close the top of the cistern, and provide a rising main from the cistern to the height at which the water is to be delivered.

The pump is either worked directly by a steam cylinder or by gearing; but the purposes for which it is best adapted, namely drainage and irrigation, render it generally more convenient and more profitable to work the pump direct by a steam cylinder. The piston rod of the latter is then prolonged and works through a stuffing-box into the cistern K, with a crosshead on the end of the rod for attaching it to the sliding barrel C, as shown in Figs. 2 and 3, Plates 5 and 6. In the double pump here shown, each barrel C is worked by a separate steam cylinder, and the general arrangement of the cylinders is similar to that adopted in locomotive engines, the two being coupled at right angles with a flywheel between them. The whole mechanism resting upon one foundation plate B is thus self-contained, and entails only a minimum outlay for foundations, whilst it may be easily shifted from one place to another.

The following practical advantages are considered to be attained by this construction of pump. By making the barrel and the bucket

in the **V** shape, the working parts have a tendency to wear themselves true and tight, instead of wearing themselves out of truth and leaky as in the case of an ordinary cylindrical bucket pump; and it appears that in practice this is found to be the actual result of working. This is an advantage of great importance in countries where skilled mechanics are scarce, and where not only are frequent repairs expensive in themselves, but the stoppages caused thereby are a source of still greater loss.

It is also found in practice that the **V** pump makes a considerably better vacuum, and consequently raises a greater column of water than pumps of the ordinary construction. It may be assumed that a vacuum of 22 feet column of water is all that may be expected in regular work from an ordinary bucket pump; whereas it has been ascertained by actual trial at Liverpool with a **V** pump constructed at the Vauxhall Foundry that it creates a vacuum of 28 feet of water, showing a difference of 21 per cent. in its favour. This may however be accounted for by the ends of the sliding barrel C, Fig. 4, Plate 7, being allowed to move close up to the bucket G; and also by the joints being all constantly immersed in the water. The advantage thus obtained may in many cases be of great importance.

The **V** pump occupies considerably less space than an ordinary double-acting horizontal pump, the difference in length for pumps of the same stroke being about equal to the length of one valvebox. The construction of the **V** pump also allows ready access to all the parts, and renders any repairs easy, and to that extent less expensive. It is only necessary to lift up the sliding barrel C, Figs. 1 and 2, Plate 5, by means of the handle F, as it is not fixed down in any way, and the whole of the working parts are then immediately exposed to view.

In calculating the percentage of loss in useful work by the friction of the moving parts in this pump as compared with an ordinary bucket pump, the co-efficient of friction of metal surfaces working under conditions similar to those of the sliding parts of the pump may be taken from Morin's experiments to be 0.16, that is the

friction is 16 per cent. of the whole pressure on the rubbing surfaces. But in the present **V** pump where the rubbing surfaces are inclined to the horizon at 45 degrees, this co-efficient has to be increased in the ratio of 1 to the square root of 2; and the corrected co-efficient is therefore taken as 0.22, that is the friction is 22 per cent. of the sliding load. Hence if w represent the whole pressure of the vacuum in lbs. upon one foot length of the sliding barrel, and l the length of stroke of the barrel in feet, the mean pressure during the entire stroke will be $\frac{1}{2} w l$; and therefore the whole amount of friction to be overcome during a complete stroke is equal to $0.22 \times \frac{1}{2} w l^2$, neglecting the weight of the sliding barrel itself.

Now taking the vacuum pressure on the sliding barrel in ordinary working to be 10 lbs. per square inch, the useful work performed in one stroke of 1 foot 4 inches with a bucket 11 inches square is

$$(11 \text{ ins.} \times 11 \text{ in.} \times 10 \text{ lbs.}) \times 1.33 \text{ ft.} = 1609 \text{ foot pounds.}$$

And the inside width of the sliding barrel measured horizontally being $15\frac{1}{2}$ inches, the work absorbed by friction is found by substituting the numerical values in the expression previously obtained ($0.22 \times \frac{1}{2} w l^2$), and amounts to

$0.22 \times \frac{1}{2} (12 \text{ ins.} \times 15\frac{1}{2} \text{ ins.} \times 10 \text{ lbs.}) \times (1.33 \text{ ft.})^2 = 362 \text{ foot pounds,}$
 which is equal to 22 per cent. of the useful work, 1609 foot pounds. The weight of the sliding barrel itself is about 350 lbs., equivalent to about 300 lbs. when immersed in water, which will give an additional friction of $0.22 \times 300 \text{ lbs.} \times 1.33 \text{ ft.} = 88 \text{ foot pounds,}$ making the total loss by friction $362 + 88 = 450 \text{ foot pounds,}$ or 28 per cent. of the useful work.

From the same data it may be calculated that in a common bucket pump the work absorbed by friction of the bucket is nearly 12 per cent., and it has been given by Rankine as 10 per cent. of the useful work, showing an advantage in favour of the common pump in friction: but in the writer's opinion the increased friction of the **V** pump as above ascertained is compensated for by the advantages attending this pump as already described. It should be borne in mind also that, since the work in friction of the sliding barrel increases as the square of the length of stroke, whereas the

useful work increases only in the simple ratio of the stroke, the percentage of loss by friction will increase in proportion to the length of stroke, unless there is at the same time a proportionate increase in the area of the bucket. For instance, with a bucket 9 inches square and a stroke of 2 feet, the capacity of stroke would be the same as in the example above given, and the useful work would consequently be the same: but the percentage of the friction as compared with the useful work would then amount to 42 per cent. It therefore follows that the ratio of the side of the square bucket to the length of stroke, which in the pump shown in the drawings is 1 to $1\frac{1}{2}$ nearly, should not be exceeded, but rather reduced. If for instance this ratio were made 1 to $1\frac{1}{4}$, the above loss of 28 per cent. by friction would be reduced to 24 per cent.

Six of the **V** pumps have been employed on the main drainage works in London for pumping out foundations, where there was a great quantity of sand mixed with the water, so that they were literally working and grinding in sand most of the time. These pumps were worked by power and used in the roughest possible manner; but they were nevertheless worked for more than six months before requiring any replaning. A number of these pumps worked by hand have also been in use for several years in farm yards, manure factories, and other places, without requiring any repairs, excepting where they are continually at work, and then only the valves require re-leathering.

The **CHAIRMAN** enquired whether the pump had been employed in other countries besides England.

Mr. BIRCKEL replied that three or four of the pumps had been made for Egypt for the purposes of irrigation, and one of them, a pump of 6 horse power, had now been at work there for twelve months. In that country along the banks of the Nile the water had generally to be raised a height of from 22 to 28 feet for irrigating the land when the river was at its lowest level; and in that case therefore the pump now described came in very conveniently,

because it could be fixed above the level of high water and would still raise the water by suction at all times from the river, even when the water was at its lowest point, without requiring to be shifted and refixed at a higher level when the water rose.

The CHAIRMAN observed that the principal advantage of the pump appeared to be the facility it afforded for getting at the working parts by simply lifting up the sliding barrel; and he asked whether the sliding barrel was made of cast iron or of brass, and whether it was not expensive in fitting up.

Mr. BIRCKEL replied that the whole of the pump was made of cast iron, and in the fitting up it was certainly more expensive than an ordinary pump, because the working faces instead of being bored had all to be planed and afterwards scraped a little. The entire cost, however, did not differ much from that of an ordinary pump, the pumps sent to Egypt having been supplied by preference on account of their special applicability to that particular case, without costing much more than ordinary pumps of the same power. Besides the facility of getting at the working parts, the other principal advantage of the V pump was the tendency of the rubbing faces to wear themselves true in working on account of their shape.

The CHAIRMAN suggested that there would probably not be much advantage in the trouble and expense bestowed on fitting up, after the pump had been at work for a time, on account of the wear of the rubbing faces, particularly if it were working in water that contained much sand.

Mr. BIRCKEL remarked that the object of planing and scraping the rubbing faces was that by their being made a good fit in the first instance there might be less chance of the sand getting into the pump.

The CHAIRMAN observed that the friction in the V pump must be considerably more than in the common pump, as had been stated; and he enquired whether this was compensated for by any greater percentage of useful effect in delivery of water.

Mr. BIRCKEL replied that the delivery of water by the V pump was 95 per cent. of the volume of the pump, giving only 5 per cent. loss of water, on account of the better vacuum obtained by the

pump working immersed in water; whereas in ordinary bucket pumps he believed there was generally 10 per cent. loss.

Mr. F. J. BRAMWELL remarked that there appeared to be three advantages attributed to the construction of pump now described, as compared with an ordinary pump: namely facility of access to the working parts, tendency of the rubbing surfaces to wear true in work, and better vacuum obtained: but in none of these respects did he think the superiority of the new pump was satisfactorily substantiated. As regarded ease of access to the working parts, that advantage was lost as soon as the pump was used as a force pump; and even confining the question to suction pumps alone, he did not consider that an ordinary pump presented any real difficulty in the way of an examination of the working parts whenever anything got out of order. In reference to the rubbing surfaces wearing true in continued working, he thought that was at best only a slight advantage and not one that would compensate for the loss by friction, which must be much greater than in a common pump; moreover it appeared a question whether it would be found in practice that the wear was equal on the piston and on the edges of the sliding barrel. As to the vacuum obtained, he considered the case of the ordinary pump was understated when it was represented as not drawing more than 22 feet height of suction; and if both pumps were immersed in water he did not see how the present pump would do more than an ordinary one. There were hardly any stationary engines where the air pump was not immersed in water, and in all cases the vacuum was much greater than what would correspond to 22 feet column of water. In the present instance, in consequence of the barrel of the pump being the moving portion, the result of working it at all rapidly would be that a large amount of power would be uselessly spent in simply agitating the water in the tank. He therefore did not see any advantage in the new pump as compared with an ordinary pump.

Mr. BIRCKEL said the advantage of ready access to the working parts was certainly lost when the pump was used as a force pump, owing to its then being covered in; and it was therefore not recommended to be used except as a suction pump. It was thought

a practical advantage to have all the working parts exposed to view by simply lifting up the sliding barrel of the pump, instead of having to break water-tight joints in order to open the valveboxes at each end of an ordinary horizontal pump; and the small cushion of air that remained in the sliding barrel when it was put down again in its place was a trifling amount compared with the quantity left in the valveboxes of an ordinary pump when they were closed after examination.

Mr. H. WOODS thought the height of lift that had been mentioned of ordinary pumps, 22 feet, was much below the average that was attained in practice. He had had one pump of ordinary construction at work for twelve months night and day, and the average height of lift had been $26\frac{1}{2}$ to 27 feet; and he had no doubt that that height of lift could be relied upon with any ordinary well-made pump.

Mr. BIRCKEL did not think that, though it might be obtained with a pump in good order, 27 feet of lift could be practically relied upon with any safety as the height for an ordinary suction pump; whereas the V pump had drawn 28 feet of water whilst standing on the pier head at Liverpool, without being primed with water to start it, and with the tank completely empty.

Mr. H. MAUDSLAY remarked that it was fortunate for the pump now described that the banks of the Nile at low water happened to be no higher than the pump could draw by suction, otherwise its advantage of facility of access would be lost. Vertical pumps for irrigation from the Nile had also been made by his own firm, of the ordinary construction: and where the banks were too high to lift the water by suction, the engine was fixed on the top of the bank, working the pump at a lower level by a long piston rod passing direct from the steam cylinder to the cylinder of the pump below. In pumping dirty water however it was difficult to keep ordinary pumps in working order, and in that respect the pump now described appeared advantageous and deserving of attention; in pumping up the sewage of London it had been found very efficient, the height to which the sewage had to be raised to reach the outlet being below the limit at which the pump would work as a suction pump.

He had seen the pump at work for this purpose, and also for pumping water out of excavations where it appeared to be raising a large quantity of sand with the water. There was however a great disturbance and splash of the water in which the pump was immersed, by the motion of the barrel sliding backwards and forwards, and that must absorb a large portion of the power to no purpose; but he had not the means of ascertaining the percentage of result to power employed.

Mr. BIRCKEL said the disturbance of the water was mainly owing to the discharge of the contents of the bucket into the tank at each stroke; and the speed of the bucket itself being not more than about 110 feet per minute, he thought it could not have any material effect in disturbing the water in the tank. The new pump was not expected by any means to supersede the ordinary pump, but was only regarded as particularly suitable for the special cases to which it had already been advantageously applied: for very large pumps he did not think it would prove efficient, on account of the increased size and weight of the sliding barrel and the consequent increased wear of the working parts.

Mr. J. PENN observed that in the new pump the pressure on the sliding barrel and consequently the friction of the working faces would increase with the height of lift, which was not the case in an ordinary pump packed with leather or having a solid bucket closely fitting the cylinder without packing.

Mr. BIRCKEL thought that in an ordinary pump having the bucket packed with leather the friction must be assumed to increase with the head of water, as he thought the pressure would act behind the packing to press it against the cylinder.

Mr. E. HUMPHRYS did not think that was the case, and it was certainly not so with metallic-packed pistons, the friction of which did not increase, however much the pressure of water might be increased; whereas in the new pump the pressure on the sliding barrel was proportional to the height of lift, and would be still further increased if the pump were used as a force pump. On the whole he thought the construction of the pump was a step backwards rather than an improvement.

Mr. J. C. WILSON observed that, in reference to the alleged tendency of the sliding barrel to wear itself tight in working, he thought this would not be altogether the case; for at the bottom of the V in which it worked any sand and dirt from the water would be liable to lodge, and would cause the point of each end of the barrel to be ground away. He enquired what had been found to be the result of practice in this respect.

Mr. BIRCKEL had not himself been acquainted with the working of the pumps for any length of time; but the pumps employed at the main drainage works in London, where there was much sand in the water, had worked six months before requiring any replaning.

Mr. E. HUMPHRYS enquired why the new pump was stated to make a better vacuum than an ordinary pump: he considered if an ordinary pump were worked under water in the same way it would produce as good a vacuum.

Mr. BIRCKEL had no doubt the vacuum would be as good in ordinary pumps if immersed in water, but they were not usually worked so, on account of the difficulty of getting to the working parts if permanently immersed; whereas the new pump was arranged to work always immersed in the water in the tank, and still have all the working parts readily accessible.

The CHAIRMAN asked what would be the advantage in working of the new pump over an ordinary one if both were immersed in water.

Mr. BIRCKEL said probably the only advantage in that case would be the facility afforded by the construction of the new pump for coming home very close to the ends of the cylinder in each stroke, leaving not more than $\frac{1}{2}$ inch clearance; as he believed a large space between the suction valve and the bucket was detrimental to the working of the pump, by preventing so good a vacuum from being obtained.

Mr. E. HUMPHRYS thought that it was of no consequence whether the clearance were 1 inch or $\frac{1}{2}$ inch, as that had no appreciable effect upon the vacuum. In a common pump working vertically the air would be discharged first, but in the new pump this would not be so perfectly effected.

Mr. E. A. COWPER considered it was a mistake to suppose the new pump had any advantage over the ordinary pump in respect of clearing itself of air by leaving only a small clearance at each end of the stroke: on the contrary he thought the advantage in this respect was on the side of the ordinary pump. For if the new pump were worked at all slowly, the air would accumulate along the top angle of the sliding barrel, and would not discharge itself with the water, on account of the horizontal position of the pump: but in an ordinary vertical pump, the air rising to the top of the water was the first to pass through the bucket, and thus the first thing the pump did in each stroke was to clear itself completely of air. Moreover in pumping water containing sand, if the sand did not lodge on the rubbing surfaces of the sides in the new pump, it would at least lodge in the bottom of the groove and cause the barrel to grind itself away at that part, and the wear would be much worse he thought than in an ordinary vertical pump packed in the usual manner, where no sand could lodge upon the sides of the barrel. For pumping very dirty water, such as sewage at drainage works or manure ponds in agricultural districts, the pump might be advantageous as affording a rough and ready means of getting at the working parts; but in other cases he thought the work would be done with less loss by friction and a smaller amount of wear and tear if an ordinary pump were employed.

Mr. BIRCKEL observed that in the new pump the space at the end of the stroke for lodgment of air might be further diminished by making the end of the sliding barrel inclined at the same angle as the bucket, so that the quantity of air remaining in the pump would be reduced to the least amount.

The CHAIRMAN remarked that there must still be some air left in the pump, however small the clearance was made; but in the ordinary pump, as had been shown, no air whatever remained, the whole of it being expelled at the beginning of each stroke.

He proposed a vote of thanks to Mr. Birckel for his paper, which was passed.

The following paper was then read:—

ON THE IMPROVED TRAVERSING CRANES AT CREWE LOCOMOTIVE WORKS.

BY MR. JOHN RAMSBOTTOM, OF CREWE.

The Traversing Cranes described in the present paper are employed in the locomotive shops of the London and North Western Railway at Crewe, where they were designed and erected by the writer. They were seen in action by the members on the occasion of their visit to the Crewe works in the excursion at the Liverpool meeting of the Institution last summer. From the interest manifested in them on that occasion and the numerous enquiries that have since been made respecting them, the writer has thought that a description of the principle and construction of these cranes may be acceptable to the members.

There are seven of these cranes in use at the Crewe works, which have been working successfully for some time, the first having now been three years in constant work. They are driven by power and are so constructed as to be driven by a light endless cord of small diameter, extending throughout the entire length of the shop traversed by the crane. This cord is driven at a very high speed, nearly 60 miles an hour; in consequence of which only a very light driving pressure is required on the shifting gear of the crane. The driving cord is kept in uniform tension by the action of a constant weight; and is arranged so as to allow of the cranes working and traversing in every direction without sensibly affecting the length of the cord.

The cranes are of two classes : Longitudinal Overhead Traversers, of which there are two pairs in the engine repairing shop, lifting loads up to 25 tons; and Traversing Jib Cranes, of which there is

one pair in the wheel shop, lifting 4 tons. The cranes are all driven by endless cords running along the top of the shops close to the roof tie-beams. The overhead traversers are worked in each case by a man seated on a platform attached to the crab and moving with it; and the jib cranes by a man standing below at the foot of the crane and walking along with it when traversing: each man having control over all the lifting, lowering, and traversing movements, by a set of handles.

The construction of the cranes is shown in Plates 9 to 18. Figs. 1 to 17, Plates 9 to 15, show the overhead traverser; and Figs. 24 to 32, Plates 16 to 18, the jib crane.

Fig. 1, Plate 9, is a transverse section of the engine repairing shop; and Fig. 2 is a plan, shortened in the direction of the length of the shop. The two pairs of Overhead Traversers A A and B B work on two parallel sets of rails, each having a span of 40 feet 7 inches and a longitudinal traverse of 270 feet. The girders forming the longitudinal rails are carried by the side walls and by columns at a height of 16 feet above the floor. The two pairs of traversers are separately worked by the endless cords C C and D D, each cord being carried down the side of the shop, and returning along the same side but at 4 feet lower level. The course of the cords is indicated by the arrows. In order to communicate motion to the traverser and crab, the driving portion of the cord is carried across each traverser to the further end and back again before passing on to the main driving pulley.

The cord is returned round a tightening pulley E, 4 feet diameter, at the end of the shop, Fig. 1, Plate 9, carried in a horizontal sliding frame F, as shown to a larger scale in Figs. 3 and 4, Plate 10. To this frame is connected a weight G, Fig. 1, for the purpose of giving the requisite tension to the driving cord, and taking up any stretching or temporary variation of length due to change of load or weather. The tightening frame F has a traverse across the end wall of the shop giving a range of 34 feet, which takes up a variation in the length of the cord equal to twice that amount.

The Traverser is shown in the side elevation and plan, Figs. 5 and 6, Plate 11: and Figs. 7 and 8, Plate 12, are transverse sections at the end and at the centre. It is constructed of two timber beams H H, trussed with wrought iron bars: and the whole is carried by four flanged wheels mounted in the cast iron carriages into which the ends of the beams H are fixed.

The Longitudinal Driving Gear is placed at J, Figs. 5 and 6, Plate 11, at the end of the traverser, and is shown to a larger scale in Fig. 13, Plate 14. It consists of a double friction disc K, keyed on the vertical spindle of the driving pulley L in which the driving cord runs. The spindle footstep and guide M are carried by the double lever N, which is connected to the short lever on the horizontal shaft O. This shaft extends across the whole length of the traverser, as shown at O O in Figs. 10 and 12, Plate 13, and is under the control of the attendant by means of the lever I sliding on the shaft along with the crab, whereby the friction disc K, Fig. 13, is raised or lowered so as to be brought in contact with the friction pulley P either at bottom or at top, according to the direction in which the traverser is required to move. The motion of the friction pulley P is reduced by the worm and worm wheel and spur gear to the pinion shaft Q, which is carried across the traverser from end to end and by means of pinions drives the carrying wheels at each end of the traverser, Fig. 6. The frictional surfaces of the driving disc K are composed of rings of alder wood cut with the fibre on end: the edges of the wood rings are bevilled, and they are secured in their places by an inner iron ring, as shown black in Fig. 13.

The pulleys for returning the driving cord from the further end of the traverser are shown separately in Fig. 17, Plate 15. They work in the inclined positions shown, in order that the cord which has passed across the traverser may be returned at $1\frac{1}{2}$ inch lower level, and at the same time in a different vertical plane, as shown at A. This is done in order to facilitate the lowering and lifting movements, as afterwards described, and further in order that the two cords which are travelling in opposite directions may not rub against each other by the swagging of either of them. These

pulleys are keyed upon wrought iron spindles running in long bearings, which are placed wholly below the pulleys, on account of the small amount of clearance between the roof principals and the pulleys, only $2\frac{1}{2}$ inches. The weight of the pulley and spindle is taken by a brass footstep. The bearings are of cast iron, and are chambered at the top for the convenience of oiling, which is done by raising the pulley by hand until the spout of an ordinary oil can will reach the chamber. In the event of the cord leaving the pulleys from any cause, guards are provided, as shown at A, in order to prevent accident.

The Crab of the traverser is shown in Figs. 9 to 12, Plates 12 and 13, which give a transverse section, a longitudinal section, and a plan. It consists of a pair of cast iron frames, carrying the chain barrel, lifting and lowering, and traversing gear; the whole being carried upon four flanged wheels running on rails bolted upon the traverser beams H H.

The Lifting and Lowering Gear is partly shown in detail to a larger scale in Fig. 14, Plate 14. The double grooved pulley R is keyed to the vertical spindle, and is put in motion when the cord is pressed into either of its grooves by the presser pulleys S and T. These pulleys are of cast iron, 8 inches working diameter, and are mounted on short wrought iron studs tapped into the radial arm Z on which they are carried, as shown in Figs. 15 and 16, Plate 14, and in the plans, Figs. 11 and 12, Plate 13. The heads of the studs are recessed to form a receptacle for oil, Figs. 15 and 16, the oiling being done from the top, through a hole drilled in the stud for that purpose. When at rest the pulleys are clear of the cord, and are therefore only running when work is being done. The stud bearings are necessarily short, in consequence of the small amount of clearance between the pulleys and the roof tie-beams, which at this point does not exceed $1\frac{1}{2}$ inches, as seen in Figs. 9 and 10. The grooves in the driving pulley R, Fig. 14, are of different diameters, whereby different velocities are obtained, the smaller being used for lowering and the larger for lifting; and as the two portions of the driving cord are running constantly in

opposite directions, the reversing is obtained by simply pressing one or other of the cords into contact with the driving pulley, by the presser pulley S or T, on the same side of the driving pulley in both cases, with a pressure proportionate to the work to be done. The radial arm Z carrying the presser pulleys S and T turns upon the spindle A, Fig. 14; and the toothed segment B, which is part of the same casting as the arm Z, gears into a rack at the end of the rod C, Fig. 11, attached to the hand lever D. The lever D is under the control of the attendant, and is held in its place by a spring catch in a notched sector.

From the driving pulley R, Figs. 9 and 12, Plates 12 and 13, the velocity of the driving cord is transmitted and reduced through the worm and worm wheel U, Fig. 12. In order to economise space the shaft of the worm wheel U is carried through the hollow shaft on which the chain barrel V and its spur wheels are mounted. The number of revolutions is further reduced by a spur pinion and wheel to the shaft W, on which slide the two pinions XX of different diameters, gearing alternately into the spur wheels YY also of different diameters, which are keyed to the chain barrel V, so as to give a greater or less purchase as required for heavy or light loads, the ratio of difference being about 4 to 1.

The Cross Traversing Gear E, Fig. 12, Plate 13, is similar in principle to the lifting gear. The two grooves of the driving pulley F are however of the same diameter in this case, the velocity of traverse being the same in both directions. The pulley F is placed on the opposite side of the driving cord to the pulley R of the lifting gear, so that the cord when used for traversing may not foul the lifting pulley. The radial arm G carrying the presser pulleys belonging to the driving pulley F is worked by a rack and segment from the hand lever J, Fig. 11, which is adjacent to the hand lever D of the lifting and lowering motion.

The cross and longitudinal traversing movements are made at the rate of 30 feet per minute. The heavy loads are lifted at the rate of 1 foot $7\frac{1}{2}$ inches per minute, and the light loads at the rate of 6 feet 5 inches per minute.

Fig. 24, Plate 16, is a transverse section of the wheel shop containing the pair of Traversing Jib Cranes; and Fig. 25 is a plan, shortened in the direction of the length of the shop. Figs. 26 and 27, Plate 17, are a vertical section and front elevation of one of the cranes. Each of the two jib cranes A A has a radius of $8\frac{1}{2}$ feet, and a traverse of 120 feet along a single rail bolted to the floor; and is guided at the top by a pair of rolled girders B B, Fig. 27, of an H section. The top of the crane carries the guide roller C, which just fits in between the two girders B and serves to support the crane laterally when lifting on either side of the rail. The driving cord is carried down the shop and back again, as indicated by the arrows in the plan, Fig. 25, just below the roof tie-beams. In its course it is passed round nearly half the circumference of the driving pulley D of each crane, by means of the two guide pulleys E E, the one crane being driven by the outgoing cord and the other by the return cord. The guide pulleys E are carried by a guide bracket upon the top of the crane post, Fig. 26, and traverse with the crane. The tightening gear F, Fig. 25, is similar in its action to that already described for the overhead traverser.

The crane is constructed of the plate box-frame G, Figs. 26 and 27, Plate 17, forming the base, and carrying the vertical cast iron pillar H, round which the outer casing and its attached jib K revolve. The driving pulley D is keyed to the vertical shaft I passing down the centre of the crane post, and from this shaft all the motions are taken by means of frictional gear. The lifting and lowering gear J, shown to a larger scale in Figs. 29 and 30, Plate 18, consists of the double friction-cone of cast iron L L, sliding on a fast key on the vertical shaft I, and moved up or down as required to bring the lower or upper frictional surfaces into contact with the single friction-cone M, from which the motion is transmitted and reduced through the worm wheel and train of spur gear to the chain barrel, as shown at J in Fig. 26. The whole is carried by the cast iron bracket N, which is bolted to the outer casing of the crane pillar and revolves with it. The bearings for the driving shaft I above and below the double friction-cone L are of cast iron; but the horizontal worm-spindle runs in a brass bush, Fig. 29, the end

pressure when lifting being taken by the collar of the bush and the end step. The driving cones are raised or lowered by means of the double lever O O and brass clutches, as shown in the plan, Fig. 30, on each side of the boss of the lower cone L. These levers are placed under the cones instead of between them, in order that any oil thrown off the collars may not affect the frictional surface. The clutch levers are connected by an external rod to the hand lever P, Fig. 26, at a convenient height for the man working the crane.

The traversing motion shown at Q in Fig. 26, Plate 17, is shown to a larger scale in Fig. 81, Plate 18. It is similar in principle to the lifting gear, consisting of the single friction-cone R keyed on the bottom of the vertical driving shaft I, which communicates a backward or forward traverse when either face of the double cone S is brought into driving contact as required; the motion being transmitted to the carrying wheels by the horizontal shaft T through the trains of worm and spur gear indicated in Fig. 26. The traversing gear is applied to both the carrying wheels in order that there may be sufficient adhesion when the load overhangs either end of the crane, which would not be the case if only one wheel were driven and the load overhung the opposite end of the crane. The double cone S is moved along the horizontal shaft T by clutch levers U, Fig. 31, in a similar manner to the lifting and lowering gear, the clutch being worked by the hand lever V, Fig. 26. The double cones S, Fig. 31, are of cast iron: but the driving cone R is composed of a cone of alder wood, which is fastened by lock nuts and studs to a wrought iron disc screwed on the coned end of the vertical shaft I, as shown in the section, Fig. 32. The traversing gear is carried by the bracket W, Fig. 31, which is bolted to the foot of the centre pillar II, Fig. 26. The bearings of the horizontal shaft T are of cast iron: and the bearing of the foot of the driving shaft I is of brass, the weight of the shaft being taken by the collar of the bush, on which rest the lock nuts screwed on the shaft at that point, as shown in Fig. 31, forming an adjustable collar for taking up the wear and keeping the driving pulley D, Fig. 26, at the right level for the driving cord. The horizontal shaft T is carried at the ends by cast iron brackets, with brass

bushes to take the end thrust in traversing: the worms are pinned on the shaft.

The jib K of the crane, Figs. 26 and 27, Plate 17, is formed of two wrought iron bars, stiffened laterally by diagonal trussing, and tied at the projecting end to the outer pillar of the crane by two tie rods. The bottom pressure of the jib is taken by the roller X, which is carried in a cast iron box bolted between the projecting sides of the outer casing of the crane, and runs on the bevelled base of the cast iron crane pillar H. The base G of the crane is sufficiently long to secure its stability when the maximum load is lifted over the rail, or lengthways of the crane base.

In these cranes, owing to the high speed at which the driving cord runs, the power is applied at a very long leverage over the load to be lifted. The velocity of the cord is in all cases 5000 feet per minute; and in the overhead traversers the heavy loads are lifted at the rate of 1 foot $7\frac{1}{2}$ inches per minute, the total leverage being slightly over 3000 to 1; so that in this case the driving power required to lift the maximum load of 25 tons is only 18 lbs. irrespective of friction. When lifting light loads with the traversers the speed of lifting is increased to 6 feet 5 inches per minute, being a leverage of nearly 800 to 1; and in the jib cranes of the wheel shop, which lift up to 4 tons, the speed of lifting is 5 feet $1\frac{1}{2}$ inches per minute, giving a leverage of nearly 1000 to 1. The actual power required in the traversers for lifting a load of 9 tons, besides the snatch block and chain, has been found to be 17 lbs. acting at the circumference of the driving pulley at the point where the driving cord acts upon it; and the total leverage over the load being 3000 to 1, the portion required to sustain the load is 6 lbs., leaving 11 lbs. as the working power required to overcome the friction of the crab gear under that load. The crab when unloaded is found to require a driving power of $1\frac{1}{8}$ lbs. to overcome its friction.

The tightening weight G, Figs. 1 and 2, Plate 9, for the repairing shop traverser, is 218 lbs., or 109 lbs. on each half of the driving cord; and this is found to be about the best working strain, for keeping the rope steady and giving the required hold on the main

driving pulley and the horizontal pulleys of the crab. The limit of the weight *G* is that required to give steadiness to the transverse portion of the cord situated between the crab pulleys and the end of the traverser, which is unsupported for a length of about 30 feet when the crab is close to one end of the traverser.

The driving cords employed are soft white cotton cords, $\frac{5}{8}$ inch diameter when new, and weighing about $1\frac{1}{2}$ ounce per foot; they soon become reduced to 9-16ths inch by stretching, and are found to last about eight months in constant work. In the overhead traverser which has been in constant work in the boiler shop for about three years with a single crab arranged to lift 6 tons, a smaller cord of about $\frac{3}{8}$ inch diameter was originally used; it was however found desirable to adopt a cord of $\frac{1}{2}$ inch diameter afterwards. The total length of each of the two driving cords in the repairing shop is 800 feet, in the wheel shop 320 feet, and in the boiler shop 560 feet. The wear and tear of the cord is considered to be mainly influenced by the bends to which it is subjected in its course; and the pulleys over which it is bent are therefore made none of them less than 18 inches diameter or about 30 times the diameter of the cord, excepting only the presser pulleys of 8 inches diameter for pressing the cord into the grooves of the driving pulleys in the overhead traversers. In the jib cranes the cord has eleven bends at all times, whether the two cranes are working or not: and in the repairing shop traversers the cord has twelve bends when both cranes are not working, sixteen when both are lifting or cross traversing alone, and twenty when both cranes are cross traversing and also lifting.

The groove of the driving pulleys is made **V** shaped at an angle of 30 degrees, and smaller at the bottom than the cord, as shown in the full size section, Fig. 21, Plate 15, so that the cord is gripped between the inclined sides and does not reach the bottom of the groove. In the guiding pulleys the groove is made half round at the bottom, with the same radius as the section of the cord, as shown in the full size section, Fig. 22; and in the presser pulleys the bottom of the groove is rounded out with rather a longer radius, as shown full size in Fig. 23.

The cord is supported at intervals of 12 to 14 feet by fixed slippers of a plain trough section, in which it lies whilst running, as shown in Figs. 18 and 19, Plate 15, and Fig. 28, Plate 17. They are of cast iron, flat in the bottom, which is $1\frac{3}{8}$ inch wide, and with side flanges, as shown in the full size section, Fig. 20; the ends are bell-mouthed, as shown in Fig. 19. These slippers are fixed $1\frac{1}{2}$ inches below the working level of the cord on the driving side, as shown in Figs. 18 and 28, so that the driving wheels pass clear above the slippers in the traversing of the crane, and lift a portion of the cord out of them successively in passing.

In experiments made with a number of slippers carrying different weights the friction between the cord and the slipper was found to be about two-fifths of the load; but as the total weight of that portion of the cord which rests on slippers is only 50 lbs. and the whole friction consequently amounts to only 20 lbs., it is not considered worth while to complicate the system by the introduction of pulleys for supporting the cord. No care in oiling is required as regards these bearing slippers used in transmitting the power along the shop, as is the case in the power cranes driven by continuous longitudinal shafting where tumbling carriers are required, or where heavy cords at low velocities are used, requiring carrying pulleys, the bearings of which need regular oiling. By means of pull cords passing from end to end of the shop, the main driving gear for each pair of traversers can be stopped at any time by the men working the traversers; so that when the cranes are not working, the whole of the high speed gearing stands idle.

The diameter of the worm wheel U of the lifting gear in the 25 ton traversers, Fig. 14, Plate 14, is $24\frac{1}{2}$ inches at the pitch line, and this is driven by a worm 3 inches diameter at the pitch circle with 1 inch pitch, the inclination of the threads of the worm to the axis of the worm wheel being 1 in $9\frac{1}{2}$ (1 in 9.4). This is found to be safely within the angle of friction, so that the worm will not slip back with any weight that it has to lift; and it thus affords a complete means of holding up the weight at any point without the use of a break, and of lifting or lowering it instantly without the

slightest jerk. The pitch of the worms has however been so arranged that in lowering but little power is required further than to put the gearing in motion. The speed of the worms at the pitch line is 833 feet per minute for the lifting gear of the 25 ton traverser, and 486 feet per minute in the jib cranes. The pressure on the teeth of the worm wheel in the traverser, when lifting the maximum load of 25 tons, is $9\frac{1}{4}$ cwts.; and in the jib crane, when lifting the load of 4 tons, it is $7\frac{1}{2}$ cwts. In the practical working of the 25 ton traversers however the strain seldom exceeds one half the above amount, since in lifting locomotive engines the two crabs are usually employed in conjunction, for facility in slinging the engine.

The action of these cranes is very smooth and easy, and all the movements are readily under control.

Mr. RAMSBOTTOM showed one of the cast iron slippers for carrying the driving cord of the crane, together with a piece of the cotton cord employed for the purpose, and also a piece that had been working on the 25 ton crane: it had not been in use many months, but was calculated from present experience to last about eight months before requiring renewal.

The CHAIRMAN enquired how long the cranes had been in use, and what was the reason for making the traversing cranes with wood trussed beams instead of wrought iron girders.

Mr. RAMSBOTTOM replied that the jib crane in the wheel shop had been in use three years, and the traversing crane about four months. The traversing cranes were made with wood trussed beams merely to correspond in character with the cranes already employed in the shop. If all the cranes had now to be constructed afresh, no doubt iron would be used throughout in preference to wood. One point of great importance to the success of the crane had been to ensure all

the pulleys being completely in balance, that they might run perfectly smooth and steady at the high velocities at which they had to be driven. This was done by balancing them carefully on a pair of parallel straight edges, adjusting their weight by a little filing and scraping, till they would remain at rest in any position indifferently, and when so adjusted they worked with great smoothness and steadiness. Without this complete balancing of the pulleys, the crane would have been a failure. In the jib cranes the driving pulleys of the lifting motion made as much as 1000 revolutions per minute; and it was by that means that the required power was obtained from so light a driving cord, and by simple contact of the cord with the pulleys, without its taking a turn round them. The friction cones for the travelling movement were made with hard wood surfaces, which were found to give a better bite than metal on metal; and there had been no difficulty in transmitting by them the full power required.

Mr. J. FERNIE had had an opportunity of seeing the cranes in use, and was greatly pleased with their construction and action. The jib crane was most convenient for taking a pair of wheels out of the lathe and conveying it to any other spot with the least possible trouble; and the traversing crane also was of great advantage for lifting an entire engine and shifting it from one line of rails to another. He enquired whether any provision was made for preventing the driving cord from slipping off the several pulleys over which it passed, and whether any accident had occurred from that cause or from the rope breaking.

Mr. RAMSBOTTOM replied that one accident had occurred with the 6 ton crane in the boiler shop not long after it began to be used, in consequence of the driving cord slipping off one of the pulleys, and sweeping the man off the crane platform. Now however guards had been added to the pulleys, as shown in the drawings, to catch the cord in the event of its slipping off, so as to prevent such an occurrence happening again.

The CHAIRMAN enquired what saving in labour had been effected in the wheel shop by the use of the new crane in place of the ordinary cranes used for such purposes.

Mr. RAMSBOTTOM replied that there were previously two dozen pairs of blocks and ropes employed in the wheel shop, requiring a large number of labourers to work them; whilst now the two traversing jib cranes alone, with two men to work them, did the whole work of the shop and very much quicker than before; and £300 a year was saved in the piecework prices of the work done in that shop alone by the use of the new cranes.

The CHAIRMAN asked whether any difficulty had been found from the dust of the shops acting upon the cotton driving cord.

Mr. RAMSBOTTOM replied there had been no difficulty from that cause: the cord was rubbed over at first with a little tallow and wax, and gave no trouble afterwards. It had been a question requiring some consideration in the first instance, what material should be used for the cord; whether leather, cotton, catgut, or hemp. He thought however nothing was so suitable for the purpose as a good cotton rope, properly made, on account of its lightness and suppleness. In using catgut the hook and eye forming the joint would give a very objectionable blow in passing over the pulleys at the high speed of running that was required.

Mr. R. WILLIAMS asked whether there was any difficulty in splicing the cotton rope.

Mr. RAMSBOTTOM had not found any difficulty arise in splicing the cotton rope; in cotton spinning machinery it was regularly done, and a good workman would make a splicing which could scarcely be distinguished from the body of the rope itself.

The CHAIRMAN enquired whether there had been any trouble with the slippers in which the driving cord was supported between the pulleys; and what form of slipper had been found best.

Mr. RAMSBOTTOM said he had first used a brass slipper, made narrower at the bottom than at the top and not giving the cord much room to play; but that shape did not answer, as the metal was found to become cut away too rapidly. Now however the slippers were made wider and flat bottomed, giving the rope free play, as it was found not at all necessary to confine it laterally. The metal now employed was also cast iron with the surface chilled, the chilled surface being smooth enough without any polishing: the friction was also less than with brass slippers.

The CHAIRMAN enquired whether the 25 tons load was allowed to descend freely in lowering the crane, and how the speed was checked in its descent.

Mr. RAMSBOTTOM replied that the load descended by its own weight after being once started, and the speed was checked simply by applying the driving cord to the pulley of the winding drum, when a very slight pressure of the cord in the V groove of the pulley was sufficient to control the motion.

The CHAIRMAN enquired whether any experiments had been made to ascertain the actual friction of the crab in the traversing crane.

Mr. RAMSBOTTOM replied that he had tried experiments upon the friction of the crab by attaching a small cord to the driving pulley, giving it a few turns round the pulley and carrying it over a fixed pulley so that weights could be hung on. It was then found that with a load of $8\frac{1}{2}$ tons on the crab it required 17 lbs. weight at the driving pulley to start this load in raising it. The theoretical power required at the driving pulley to balance the load of $8\frac{1}{2}$ tons was 6 lbs., showing that the friction of the worm and the rest of the gearing was 11 lbs. in that case, or nearly twice the theoretical power. The greater friction of the new crane as compared with ordinary cranes was indeed its only drawback; but that was more than compensated for by the simplicity of construction of the new crane, and the fact that in consequence of this increased friction it required no break to hold the load, which was an important advantage over the old cranes. Moreover if the cord were driven at a much lower velocity, in order to reduce the friction by diminishing the multiplying power of the crane it would be necessary to put a much higher tension upon the cord, which would then have a tendency in the present arrangement of the driving gear to throw the crane out of line and cause it to run off the rails. It was therefore important to adhere to the high velocity of driving cord that had been already adopted.

Mr. E. A. COWPER observed that a light driving cord was the only plan compatible with a high speed of driving, as a heavy cord or chain would soon wear out by its own weight. The mode of reversing the motion, by merely deflecting the driving cord into one

or other of the two grooves of the driving pulleys, was exceedingly simple and efficient; and the arrangement was also very simple for increasing the length of surface of contact of the cord with the pulley to meet the requirements of a heavier load. He enquired whether the weight of 17 lbs. at the driving pulley in the experiment that had been described was sufficient to start the crane.

Mr. RAMSBOTTOM replied that the weight of 17 lbs. at the driving pulley of the crane was just insufficient to start the load at $8\frac{1}{3}$ tons on the crab from a state of rest, but if once started it would keep it going, the theoretical force required to balance that load being only 6 lbs.

Mr. E. A. COWPER remarked that the friction of the crane in the experiment was illustrated by the skidding of an engine on the rails when the wheels had once started slipping; and probably in the case that had been described the actual friction of the crane when once in motion was not much more than 6 lbs. in addition to the theoretical power required to balance the load of $8\frac{1}{3}$ tons; while from that force, 12 lbs., up to 17 lbs. at the driving pulley the crane would either run or stand. He enquired whether the jib cranes in the wheel shop were balanced by a load of ballast on the tail of the crane.

Mr. RAMSBOTTOM replied that the jib cranes were not counter-balanced, the weight of the frame itself being sufficient to steady the crane under the heaviest loads it had to lift.

Mr. E. H. CARBUTT enquired whether the cranes made much noise in working, on account of their high speed. He had seen a crane of similar construction at work in a foundry, and the noise it made was very objectionable.

Mr. RAMSBOTTOM thought the noise in that case must have arisen from a want of balance in the moving parts; but in the present cranes, with the driving pulleys all properly balanced, there was no objection from noise, the cranes working very smoothly and quietly.

The CHAIRMAN proposed a vote of thanks to Mr. Ramsbottom for his paper, which was passed.

The Meeting then terminated.

PROCEEDINGS.

5 MAY, 1864.

The GENERAL MEETING of the Members was held at the house of the Institution, Newhall Street, Birmingham, on Thursday, 5th May, 1864; JOHN RAMSBOTTOM, Esq., Vice-President, in the Chair.

The Minutes of the last Meeting were read and confirmed.

The CHAIRMAN announced that the Ballot Lists had been opened by the Committee appointed for the purpose, and the following New Members were duly elected :—

MEMBERS.

WILLIAM CODDINGTON,	Blackburn.
ZERAH COLBURN,	London.
EDWARD CROWE,	Middlesborough.
JOHN DEWHURST,	Sheffield.
THOMAS FROST,	Derby.
RICHARD HEATHFIELD,	Birmingham.
THOMAS HENRY MAUDSLAY, JUN.,	London.
SAMPSON MOORE,	Liverpool.
COLONEL M. SAID, BEY,	London.
JOHN SANDERSON,	Whitehaven.
JOHN SEDDON,	Wigan.
JAMES FOLLIOTT STOKES,	Shrewsbury.
BERNARD PEARD WALKER,	Wolverhampton.
ISAIAH WHITE,	Seville, Spain.
THOMAS WILLIAM WORSDELL,	Birmingham.

HONORARY MEMBERS.

JOSEPH W. BRANSON,	Birmingham.
JOSEPH WELLS HORNBLOWER, . . .	Birmingham.
DAVID MURRAY,	Birmingham.

The following paper, communicated through Mr. Charles F. Beyer of Manchester, was then read :—

DESCRIPTION OF HARRISON'S CAST IRON STEAM BOILER.

BY MR. ZERAH COLBURN, OF LONDON.

The importance of high pressure steam as a condition of steam engine economy has long been understood. Trevithick as early as 1804 worked an engine at what was then regarded as an enormous pressure, 50 lbs. per square inch. His American contemporary, Oliver Evans, recommended a still greater pressure, 150 lbs. per square inch, cut off at one third of the stroke; and from the records of the department for supplying Philadelphia with water, it appears that Evans actually employed not only this pressure, but still higher pressures, on the large scale of pumping engines. In 1817 one of his engines was started at the Fairmount Waterworks, Philadelphia, and was worked regularly at from 194 to 220 lbs. per square inch; the engine cylinder was 20 inches diameter and the stroke of the piston 5 feet, the usual working speed being 25 revolutions per minute; steam was supplied from four cylindrical boilers, 30 inches diameter and 24 feet long, fired externally. A Boulton and Watt engine of 44 inch cylinder and 6 feet stroke had been started two years previously at the same waterworks, having a cast iron boiler with vertical wrought iron flues, with a steam pressure of only $2\frac{1}{2}$ to 4 lbs. per square inch. Both these engines pumped through a 16 inch main, 239 feet long, into a reservoir 102 feet above the level of supply. Trials of twenty four hours' duration showed that the low pressure engine had rather the advantage over the other in point of economy: the former pumped into the reservoir in twenty four hours 1,763,104 gallons of water with a consumption of 896 cubic feet of wood, being 1968 gallons per cubic foot; while the high pressure engine, in raising 3,124,891

gallons through the same main, consumed 1664 cubic feet of wood, or at the rate of 1878 gallons per cubic foot.

Steam of rather more moderate pressures than Evans employed, or of about 100 lbs. per square inch, continued subsequently to be employed in America, notwithstanding the frequent explosions of high pressure boilers. In England the boilers for Trevithick's engines were made of large diameter and of cast iron; and many of them were made at the Bridgenorth Foundry with an internal diameter of 8 feet, and in 8 feet lengths, which were connected together by flanges and bolts up to any length required. Such boilers were unquestionably dangerous, although many wrought iron boilers of equal or greater diameter and probably of less strength are worked up to the same pressure now. An occasional explosion of a Trevithick boiler, and the influence which the practice of Boulton and Watt then exercised, soon occasioned a general return to low pressures, except in Murray's, Stephenson's, and Hedley's locomotives, which were worked regularly at 50 lbs. per square inch.

Within the last thirty five years however, or in fact coincident with the progress of improvements in boiler making, there has been a corresponding tendency to return to high pressures. The locomotives on the Liverpool and Manchester Railway worked in 1830 with steam of 50 lbs.; by 1843, pressures of 75 lbs. and 80 lbs. had become common upon railways: 100 lbs. to 110 lbs. was regularly maintained in 1851; and at the present time 120 lbs. is the usual, and 160 lbs. an occasional pressure in locomotive boilers. The last named pressure is not very much below that recommended for locomotives by the late Jacob Perkins, nearly thirty years ago, who preferred steam of 200 lbs. cut off at one eighth of the stroke. In marine engines an ordinary working pressure of 25 lbs. has been reached, while some of the Liverpool and Montreal vessels are worked at 40 lbs., and the Pacific Mail steamers at 50 lbs. per square inch. For ordinary land engines even 100 lbs. pressure has been adopted in many cases; and this and still higher pressures are already employed by some makers of portable and traction engines.

Although the construction of boilers has been much improved, in order that higher and higher pressures might be maintained, it is certain that great room for improvement is yet left. The old boiler fired externally is objectionable; while for internal firing it is necessary either to have a firebox and tubes, or to have flues large enough to allow the fireplaces to be formed within them. The multitubular boiler, unless supplied with good water, requires much care to prevent choking with scale; and its repairs are in all cases greater than those of the Cornish and Lancashire boilers. The Lancashire or two-flued boiler is that most used in the manufacturing districts; but its diameter is necessarily so large as to render it imprudent in most cases to load it with steam of much more than 50 lbs. pressure, and this is not the high pressure to which present steam engine practice is tending. A diameter of 7 feet is common for Lancashire boilers; and if made of $\frac{1}{2}$ inch Staffordshire plates, single-rivettèd, their bursting pressure may be taken as 333 lbs. per square inch. This estimate is made upon Mr. Fairbairn's usual allowance of a loss of 44 per cent. in the strength of the solid plate at single-rivettèd seams; and the estimate of course assumes that no flaws are hidden in the iron, and that the workmanship is good, the rivetting being fairly done so that the boiler shall not have been injured by the use of the drifting tool. This then is the limit of strength when the boiler is new; and it would be manifestly imprudent to press to more than 50 lbs. or at the utmost 70 lbs. a boiler which was certain to burst at 333 lbs., and to be permanently injured by a much lower pressure. It is shown moreover by the reports of the Manchester Boiler Association that many boilers are subject to weakening from corrosion or furrowing of the plates. A leakage of steam, however slight, from any part of the boiler into the adjacent setting is almost certainly attended with corrosion. Condensed steam, that is distilled water, appears to exercise a strong solvent power upon iron, as is known in the cases of boilers supplied with very soft water or peat water or more especially those fed with water from surface condensers. As has been shown in the case of several recent boiler explosions, the thickness of boiler plates is often wasted nearly through by unsuspected corrosion.

This source of danger to a certain extent neutralises the means occasionally resorted to for securing great strength in boilers, such as the use of steel or homogeneous metal plates, double rivetting, thick-edged plates, welded joints, &c.

Whenever a failure unhappily occurs in the plates or rivetting of a boiler, the destructive effect appears to depend, not merely upon the pressure under which the failure takes place, but also and probably still more upon the quantity of water contained in the boiler. The effect of the boiling water in an explosion may be considered as analogous to that of gunpowder; and, as in the case of gunpowder, the effect is proportionate to the quantity exploded. It is preferable therefore, while increasing the strain upon boilers by increasing the pressure of the steam, to diminish at the same time the quantity of water contained in them; doing so of course without exposing any part of the boiler to the direct action of the fire on one side of the plates where there is no water present on the other. In a large Lancashire boiler the object of carrying so much as from 15 to 20 tons of water is mainly to ensure that all the heating surfaces shall be fairly covered; and with this construction of boiler a smaller quantity of water will not answer that purpose. A certain body of water is indeed necessary to prevent sudden fluctuations in the pressure of steam; but in the majority of cases a few hundred gallons at most is quite enough for this purpose; and especially where means are employed for drying or superheating the steam, there will be neither sudden alterations in the pressure nor difficulty in respect of priming, even where only a small body of water is maintained in a boiler and where the water level or surface from which the steam rises is of but small area. Moreover it should not be forgotten that with all steam boilers the whole or nearly the whole of the fuel employed in raising steam from cold water at starting is lost when the boiler stops work at the end of the week, especially where the boiler has then to be blown out. To heat 20 tons of water from its ordinary temperature in the open air to 300° Fahr., the temperature corresponding to a steam pressure of 50 lbs. per square inch, will seldom take less than 15 cwt. of coal, in addition to that lost in heating the brickwork setting of the boiler.

On this account therefore it is desirable to work boilers with as small a quantity of water as will suffice for every necessary purpose.

The Cast Iron Boiler about to be described has been constructed with reference to the foregoing considerations. It was the object of the inventor, Mr. Joseph Harrison of Philadelphia, United States, to provide great strength against bursting, and to obtain also a large extent of heating surface in proportion to the weight and external dimensions of the boiler: it was important moreover to obtain perfect circulation for the water. The experience with this boiler for several years in America and for upwards of two years in London and Manchester, in one case with a boiler supplying steam to the extent of 200 indicated horse power, has proved that these objects, as well as other important advantages, have been secured.

The boiler is shown in Plates 19 to 23. Fig. 1, Plate 19, is a longitudinal section; Fig. 2, Plate 20, a front elevation; and Figs. 3 and 4, transverse sections. Figs. 5 and 6, Plates 21 and 22, are longitudinal and transverse sections to a larger scale.

The several parts of the boiler received different forms in the earlier experiments several years ago, but these led to the adoption of the present hollow cast iron spheres, connected by hollow necks, and secured together by bolts, as shown in the longitudinal sections, Figs. 1 and 5, Plates 19 and 21. Figs. 7, 8, and 9, Plate 23, are enlarged sections of one of the castings, which includes four spheres, each 8 inches external diameter, $\frac{3}{8}$ inch thick, and connected by necks of $3\frac{1}{8}$ inches opening. Each of these castings is called a "unit." Each "unit" of four spheres has eight openings, $3\frac{1}{8}$ inches internal diameter, the edges of which are faced up to a true surface, so as to bear fairly upon the corresponding faced surfaces of the adjoining units. Each joint has a shoulder and socket, as shown full size in the section, Fig. 10, Plate 23, so as to steady the units in their place. Steam-tight caps are provided to cover the external openings, as shown in Figs. 8 and 9; and the whole series of units, forming a vertical slab of rectangular or other shape, are held together by bolts of $1\frac{1}{4}$ inch diameter, passing inside the spheres and through the water or steam which they contain.

Each slab, whatever number of units it may be composed of, may be regarded as a separate vessel, throughout which the water or steam can circulate freely, both vertically and longitudinally. Any number of slabs may be placed side by side in the same fireplace; in the boiler here shown there are eight, as seen in the transverse sections, Figs. 3, 4, and 6, Plates 20 and 22. They are connected together by a feed-water pipe A at the bottom and by a steam pipe B at the top. The water level is usually maintained so that about two thirds of the whole number of spheres will be constantly filled with water, as shown in Figs. 5 and 6, and by the dotted line in Fig. 1; the remaining spheres forming a steam space. The full heat of the fire is prevented from coming upon the upper spheres which contain only steam, by small firebrick screens or cast iron plates C C, Figs. 5 and 6, which are placed loosely between the slabs, a little below the water level, so as to confine the direct action of the heat chiefly to the spheres filled with water. The upper spheres are at the same time enveloped in an atmosphere so hot as to ensure the steam being completely dried. The slabs are fixed with an inclination in the direction of their length, as shown in Figs. 1 and 5, sufficient to ensure the complete drainage of all the spheres when the boiler is blown out. This inclination serves at the same time to bring the largest body of water to where the action of the heat is most direct, and to provide the largest steam space over that part of the boiler where ebullition is probably the least active. The earlier experiments have shown that, although the units may be bolted together into slabs of a total length of even 20 feet, a length of 9 feet is preferable, since the strain upon the bolts in screwing up is correspondingly less: and as in the latter case there is no observable tendency to sag in the centre, the complete tightness of the joints is thereby secured.

The spheres weigh each about $22\frac{1}{2}$ lbs., a unit of four spheres weighing rather more than $\frac{3}{4}$ cwt. Hence there are very nearly one hundred spheres to the ton; and it has been the habit thus far to rate these boilers by their weight, as a 4 ton boiler, an 18 ton boiler, &c. The nominal horse power of the boiler may be generally taken as three times its weight in tons. Thus a 10 ton

boiler may be rated as of 30 nominal horse power; and from experiments it appears that a boiler of this weight may be counted upon to evaporate 40 cubic feet of water per hour, corresponding to about 80 indicated horse power. Each sphere contains seven pints of water, a unit of four spheres containing $3\frac{1}{2}$ gallons. The external surface of each sphere is rather more than $1\frac{1}{4}$ square feet, and the internal surface a little more than $1\frac{1}{8}$ square feet. In round numbers it may therefore be said that each sphere presents a square foot of heating surface and contains a gallon of water; while a ton of one hundred spheres represents three nominal horse power, the proportion of weight to power being thus about the same as in Lancashire boilers of the ordinary type.

Although it cannot be said that cast iron is in itself a strong material for boilers, yet it will be seen that, in the form now described, it affords greater absolute strength against bursting than is possessed by any form of plate iron boiler at present in use. The units are cast upon green sand cores, so placed that they cannot alter their position in the flask by any force short of what would be sufficient to crush them to pieces. The thickness of metal in the spheres is therefore uniform throughout, as has been proved by breaking great numbers of units taken at random. In a unit of four spheres, each sphere having an internal diameter of $7\frac{1}{4}$ inches, the whole area of the plane in which a bursting pressure would act, taken through the eight openings of the four spheres, as in Fig. 8, Plate 23, is 220 square inches; while the least section of iron resisting this pressure in the same plane is $27\frac{1}{2}$ square inches. The iron employed is an equal mixture of Glengarnock, Carnbroe, and scrap: a mixture selected for its free running quality, and much used for small machinery castings. Its tensile strength may be safely taken as $5\frac{1}{2}$ tons per square inch. At this rate the bursting strength of the units would be 1540 lbs. or nearly three quarters of a ton per square inch internal pressure. The first experiments actually made to test the bursting strength of the units were made more than two years ago in Brussels for the Belgian Minister of Public Works. In this case a pressure of 98 atmospheres or 1440 lbs.

per square inch was applied. This was as high as the force pump employed could go, but the spheres were not burst.

A further series of experiments for the purpose of testing the bursting strength of the cast iron spheres have recently been made at the Gorton Foundry, Manchester. A high-pressure Schaeffer's gauge graduated to 1000 lbs. per inch was attached to one of the units or castings of four spheres, to which the caps had been accurately ground, and water pressure was then applied by means of a force pump. The pointer of the gauge passed the 1000 lbs. mark to an extent indicating from 1150 lbs. to 1200 lbs., but the spheres did not burst. The pressure gauge was then checked by comparison with a Bourdon gauge up to 500 lbs. per square inch, and found to agree within 10 lbs. By calculation from the weight applied to the force pump lever and the dimensions of the pump it was estimated that the total force applied, including the friction of the pump, was about 1470 lbs. per square inch. Another similar casting was afterwards tested in the same way with a similar result. The castings were subsequently broken with a sledge hammer, and showed a uniform thickness at all parts and a good quality of iron. A safety valve was then arranged for the purpose of ascertaining the bursting strength of the spheres; the seat of the valve was 1.4th square inch area, and the head of the valve $1\frac{1}{4}$ inch diameter, the valve being ground carefully to its seat. The spheres were burst at a pressure calculated at 1850 lbs. per square inch; but on comparing the safety valve with a pressure gauge it appeared that water must have worked its way over the ground seating of the valve, allowing the pressure to act upon a greater area than 1.4th square inch, and that the true pressure could hardly have been so much. The head of the valve was then reduced to a diameter of $\frac{7}{8}$ inch, and the spheres were burst at a calculated pressure of 1650 lbs. per square inch; but it was still found that some water must have worked over the valve seating, and the experiments with the safety valve were not therefore altogether satisfactory, but there appeared no reason to doubt that the bursting pressure was not far short of 1500 lbs. per square inch. All these experiments were made upon castings having their covering caps ground carefully to

them, and the bolts were only about 9 inches long between the caps covering the opposite openings of the units. When however a slab of say one hundred spheres is bolted together, the bolts being upwards of 9 feet in length become so far stretched by a strain considerably below the bursting pressure as to cause the joints to open everywhere and relieve the pressure. In this way every joint becomes a safety valve. This never occurs with any practicable steam pressure, but it did take place in many of the earlier experiments made to burst the spheres, although leakage seldom commenced until a strain of nearly or quite half a ton per square inch had been applied.

The above experiments were all made with new castings, and at the time they were made no other spheres could be had which had been more than twelve months in use; and the condition of these was clearly the same as when new. It would appear therefore that the boiler now described possesses the same degree of safety under a pressure of 230 lbs. per square inch as a 7 feet Lancashire boiler under a pressure of 50 lbs. If however one of the units of the cast iron boiler should burst, it could not do more than empty itself, and open one or more $3\frac{1}{8}$ inch apertures into the units adjacent to it; whereas if an ordinary boiler, containing say 20 tons of highly heated water in one compartment, should burst, the consequences would be most disastrous. In some of the earlier boilers of the kind now described the setting was such that an excessive strain was brought upon one or more joints; and here, in order to prevent leakage, the bolts had to be tightened with great force, and in two or three cases castings forming a part of the boiler were thus cracked from one joint to another. The consequence was an escape of steam or water, but no further damage ensued. In one of these instances a unit thus cracked was worked continuously for three days, and it might perhaps have been worked for a still longer time; but it was thought prudent to replace it by a sound casting. No instance of a fracture has occurred in the cast iron boilers with the present mode of setting, and all the boilers of this kind yet erected are quite free from leaks at the joints.

The bolts securing the castings together have a strength much beyond even that at which the spheres would burst. They are under a certain initial strain before any pressure is raised in the spheres ; but the amount of this initial strain is known and under control, for in screwing up the slabs a 27 inch wrench is employed, and the strength of but one man is applied to it. If however a great strain be put upon the bolts, the crushing strength of the castings is found to be greater than the tensile strength of the bolt. In a series of experiments made at the manufactory of these boilers by Mr. Lunders a slab of units bolted together to a length of 9 feet was screwed up with great force ; a wrench 10 feet long was employed and the force of three men applied. In every case the castings were compressed to the extent of 1-8th inch in a length of 9 feet, when the bolt commenced to stretch, and after elongating $1\frac{1}{4}$ inch it broke. This experiment was repeated twelve times with the same result, the castings remaining uninjured. The castings when laid loosely upon a brick pavement require a powerful overhead blow from a heavy sledge hammer to break them. They have also been heated in a forge to a bright cherry red colour, and then plunged in cold water, without cracking : though there is no doubt that the iron was seriously injured by this treatment, and it might have been expected that the spheres would break to pieces. Their endurance is to be referred to their form and to the tough quality of the metal from which they are cast ; a sharp blow with the edge of a hammer indents the iron nearly the same as if it were boiler plate.

It might have been apprehended that the expansion of the castings, when in service in a boiler, would be such as to cause unequal strain upon the joints. No leakage however can be detected at any of the joints of a single slab of castings ; and as each slab is supported chiefly at its lower corner, and all the slabs of a boiler are separate from one another, except at a single point at top and bottom where the steam and water connections are respectively made, it is found that the slabs are under no injurious strain. Moreover all the spheres have a considerable amount of elasticity under strain, which would assist in compensating for unequal expansion, did this exist. These conclusions as to the

effect of expansion are derived from an experience of $2\frac{1}{2}$ years with one of these boilers of 12 horse power at the chemical works of Messrs. Denton at Bow Common, London; two boilers, one of 50 horse power and the other of 12 horse power, at the engineering works of Messrs. Hetherington, Manchester; and a 12 horse power boiler at the manufactory of these boilers, Openshaw, Manchester. The two boilers at Messrs. Hetherington's are often worked, collectively, up to 200 indicated horse power; the first was erected at their works about eighteen months ago. The boilers of this construction were originally bolted up in slabs 25 feet long, where considerable power was required; but in such cases it is now preferred to employ two or three slabs, one behind the other, as shown in Fig. 1, Plate 19, each slab being 8 or 9 feet long. When this arrangement was first employed, the steam space of the back slab was connected by a pipe with that of the front slab, the steam being taken off to the engine from the front slab alone; and the steam pipes connecting the front and back slabs being made of cast iron, and of a form which did not allow of the unrestricted expansion of the slabs, some of the pipes consequently cracked; but they are now made of wrought iron and of a curved form, as shown in Figs. 5 and 6, Plates 21 and 22, so as to yield readily to a moderate strain.

The inventor of this boiler, Mr. Harrison, had from the first expected an entire freedom from corrosion of the spheres; and the experience thus far has borne out this anticipation. Cast iron is well known to endure much better than wrought iron under the action of flame, water, and other corrosive influences. In the case of gas retorts for instance, plate iron would be immediately burnt through; whereas, previous to the introduction of clay retorts, cast iron answered very well. The pipes for heating the blast of blast furnaces were originally made by Mr. Neilson of plate iron; but although the blast was then heated to only 350° , it immediately became necessary to resort to cast iron heating pipes. The superior durability of cast iron forge tuyeres, especially when made hollow and lined with water, is also well known. In the case of the present boiler many castings have been purposely removed and examined

after being at work ; but their weight has been found the same as when they went in, and the joints showed no degradation of their original surface.

The question which caused most apprehension in the first instance in connection with this boiler was the possibility of maintaining a clean surface within the spheres. The cast iron boiler may be said to belong to the class of water-tube boilers or those having small water cells. This class of boiler is about sixty years old, for one was fitted in Meux's brewery in London by Arthur Woolf in 1804 ; and in the same year a small screw steamboat was worked on the river Hudson by John C. Stevens of New York, the engine of which was made by Boulton and Watt, while the boiler had 81 water tubes, 1 inch diameter and 2 feet long. From the first however such boilers have generally failed on account of defective circulation and the difficulty of keeping the tubes free from internal deposit. Many attempts have been made to remove this difficulty. Circulating pumps have been employed in addition to the ordinary feed pump, to maintain a constant circulation of water through the tubes. The boilers of the first American steam fire-engines were thus constructed, and some time since a description of such a boiler was given in this Institution. Other forms of water-tube boilers have been made with different means for promoting a circulation of the water ; but in all cases the whole of the inorganic matter contained in the feed water must remain in the boiler, unless it be blown out while working ; and in the case of some salts held in solution by ordinary boiler water, these are inevitably and almost irremovably deposited upon some part of the internal surfaces. The boiler now described forms no exception to the general experience in this respect. The water with which Messrs. Hetherington's boilers and indeed most of those in Manchester are fed is such as to deposit a hard scale 1-8th inch thick after a few weeks' working. A tool had been contrived with steel scrapers so hinged that it might be entered through any of the openings in the spheres of the cast iron boiler and be then expanded out to the internal circumference of the spheres : by then working this tool within

the sphere the scale would be removed so that it could afterwards be blown out.

It has unexpectedly turned out however that no occasion has arisen for the use of this scraping tool. The boiler was blown out regularly at the end of every week, and it was found that the supply of steam continued good without any use of this tool, and that none of the spheres became overheated or leaking. After ten months' work of the 50 horse power cast iron boiler at Messrs. Hetherington's, it was desired to increase the boiler power at their works; and as the boiler then in use there was formed of units having only two spheres each, it was replaced with a new boiler having four spheres in each unit, excepting the units employed for breaking joint, which had two spheres as before. On taking down the old boiler little or no scale was found in any of the spheres, two of which, in the same condition as when taken down, are now exhibited to the meeting. One taken from the 12 horse power boiler at the same works was broken by the writer and is also exhibited. This was purposely taken from near the bottom of the boiler, and it had worked constantly for eight months without any examination. It will be seen that the broken pieces, which are in the same condition as when the casting was taken out and broken, contain no scale. In taking down the old 50 horse power boiler however a lump rolled out from one of the spheres; and this, the only piece of the kind found, is also exhibited. It consists of scales seldom larger or thicker than a sixpence, loosely cohering together by a clayey deposit from the water; in the mass it is very friable, but the fragments of scale are themselves of the same obdurate sulphate of lime as that which hardens in nearly all other boilers in the same district; yet these scales have in every case separated from the iron before attaining a thickness greater than 1-16th inch. It cannot be because the boiler is of cast iron that it so readily sheds its scale; for Trevithick's boilers and the cast iron "elephant boilers" long ago made by Mr. Hall of Dartford enjoyed no immunity in this respect as compared with wrought iron boilers fed with the same kind of water. In the Lancashire district too, the cast iron pipes of the apparatus used for heating the feed water for boilers are subject to choking with

scale in the same manner as if they were made of wrought iron ; and in some cases they become completely choked and can be cleared only by a boring tool. The fact that the spheres of this boiler shed their scale is not to be referred therefore to their being made of cast iron. It might perhaps be imagined that the water is occasionally driven from the internal surfaces, and that the consequent expansion of the spheres and their subsequent contraction on the return of the water would account for the scale becoming loosened and broken off. But the spheres show no evidence, as in this case they might be expected to do, of any irregular action of the fire ; and moreover those of the spheres which are placed far behind, where the action of the heat is moderated, are equally free from scale. It appears to be more probable that, as the spheres expand at all parts, and in cooling contract equally at the same parts, the scale is detached and crushed in this process of contraction. If this conjecture be correct, the unexpected separation of the scale may be attributed to the form and dimensions of the spheres themselves.

Whatever explanation may be offered, it is certain that with foul water and such as gives much trouble in other boilers the scale breaks off freely into small pieces in this cast iron boiler ; and this is perhaps one of its most valuable properties, although quite unforeseen. It would not be prudent to anticipate the result in the application of this boiler to marine purposes ; but in all the land boilers of this construction it has been found that with blowing off once a week they may be worked for an indefinite length of time without any accumulation of scale. It will be seen how readily this boiler may be laid open for examination, and it was recently thought expedient to open the large boiler at Messrs. Hetherington's works for this purpose. A small quantity of loose and broken scale, not above a tablespoon full, was found in each of the units examined ; but their internal surfaces, so far as they could be seen, were entirely clear.

The evaporative efficiency of the cast iron boiler depends, as in the case of all other boilers, upon the amount of heating surface exposed in proportion to the consumption of a given weight of fuel

in a given time. The boiler by which Messrs. Hetherington's works are now driven supplies an amount of steam which a single Lancashire boiler, 7 feet diameter, 30 feet long, and weighing 14 tons, was found inadequate to produce. Both the original and the present boiler are in connection with a chimney 165 feet high, which affords an excellent draught. The original boiler had two flues, each $2\frac{1}{2}$ feet diameter and enlarged at the fireplace to 3 feet. The area of the firebars was 36 square feet, and the total "run" of the heat was 90 feet in length before quitting the boiler. The cast iron boiler now in use has about 1800 spheres, weighing 18 tons, and presenting about 1600 square feet of surface in the water spheres and about 700 square feet in the steam spheres; the area of firegrate is 33 square feet. The usual quantity of water carried is 147 cubic feet or rather more than 4 tons, the quantity usually carried in the original Lancashire boiler being nearly 20 tons. The external dimensions of the present boiler are considerably less than those of the Lancashire boiler. Rather more than 3 cwts. of coal are required in the cast iron boiler for raising 50 lbs. steam from cold water, and the time occupied is about half an hour. In order to ascertain the exact evaporative efficiency of the boiler, it would be necessary to begin the observations when it was in full work, and to continue them uninterruptedly for a considerable time. As the boiler is now worked, the fires are lighted on Monday morning and let down on Saturday afternoon; but they are banked every day at breakfast time, at noon, and at night. The mass of brickwork which is thus alternately heated and cooled with the boiler is very great; and the quantity of heat that enters it, which is for the most part wasted on stopping, is correspondingly large. Except at the beginning of the week, the temperature of the water in the boiler on starting in the morning is at least 212° , while the feed water from the hot well is usually between 90° and 100° .

In February last the writer made a series of careful observations upon the working of this boiler, more especially to ascertain its evaporative efficiency. The coal was of good quality, from the Oldham Pits, and was carefully weighed; and the feed water was made to pass through one of Worthington's water meters on its

way to the boiler. The indications of the meter were ascertained to be accurate, by its registration of $147\frac{3}{4}$ cubic feet in filling the boiler up to a point known to correspond exactly with that quantity. In the first day's trial, between 5.40 a.m. and 12.55 noon, with an interval for breakfast, the whole consumption of coal was 38 cwts. and of water 442.7 cubic feet. If this quantity of water evaporated were to be divided by the gross consumption of coal, the result would be only 6.48 lbs. of water evaporated per lb. of coal : but in heating the boiler and its contents to the working point, and in the loss at breakfast time, the consumption of coal was such that 24 cwts. were burnt for evaporating the first 200 cubic feet of water ; while the remaining 14 cwts. held out for the time during which 242.7 cubic feet of water were evaporated. Allowing for the lowering of the fires at the hour for stopping work, the quantity of coal actually expended in evaporating the 242.7 cubic feet of water may be taken as 16 cwts., corresponding to an evaporation of 8.43 lbs. of water per lb. of coal. Towards the end of the day's trial, in a period of 1 hour 40 minutes, 8 cwts. of coal were burnt and 142.7 cubic feet of water evaporated : but as this would correspond to an evaporation of 9.91 lbs. of water per lb. of coal, a portion of the water must have been evaporated at the expense of the heat already in the water and in the boiler and its brickwork setting. That this was the case is shown by the fact that in the last 50 minutes of the trial only 2 cwts. of coal were burnt while 80 cubic feet of water were evaporated ; a proportion which, were the total evaporation due to the quantity of coal actually burnt within the same period of time, would have corresponded to an evaporation of 22 lbs. of water per lb. of coal, which would of course have been impossible. In making these observations there was always the uncertainty attending the quantity of coal that should be assigned to heating the boiler, and its contents and setting, up to the working temperature, and the quantity that was to be set down to evaporation alone.

In the second day's trial, starting on Monday morning with water at about 45° temperature, 5 cwts. of coal was consumed in raising steam to the working pressure, the time occupied being half an hour.

Including the coal burnt in raising steam, 2 tons 18 cwts. were consumed during the day, and 657 cubic feet of water were evaporated, corresponding to an evaporation of 6.30 lbs. of water per lb. of coal. But as a greater quantity of heat was manifestly left in the boiler and brickwork on stopping at night than when work was commenced in the morning, and as there was a waste of heat during the breakfast and dinner hours, not more than $2\frac{1}{2}$ tons of coal at most can be fairly charged to the water evaporated, and this is probably in excess of the actual quantity. This corresponds to 7.31 lbs. of water evaporated per lb. of coal. The evaporation from noon until the hour of stopping at night averaged 7.56 lbs. of water per lb. of coal, while for the last four hours of the experiment the apparent rate of evaporation was 8.71 lbs.

In the third day's trial, steam having been kept in the boiler over night, the consumption of coal from 6.0 a.m. till 2.30 p.m. was 2 tons 6 cwts., which included the loss during the breakfast and dinner hours, and the evaporation was 519 cubic feet, corresponding to 6.27 lbs. of water evaporated per lb. of coal.

In a whole week of $57\frac{1}{2}$ hours an average of 77 cubic feet was evaporated per hour, the maximum evaporation being about 82 cubic feet per hour, and the average consumption of coal was 6.25 cwts. per hour. This corresponds to 6.85 lbs. of water per lb. of coal; but, allowing for the sources of loss already pointed out, nearly 8 lbs. may be taken as the effective rate of evaporation. The temperature of the escaping gases, as indicated by Gauntlett's pyrometer, was about 600° on the average, the steam of 50 lbs. pressure showing the normal temperature of about 300° by a thermometer inserted for the purpose. The average rate of combustion was 21 lbs. of coal per square foot of firegrate per hour. When the fires were not driven so hard the rate of evaporation per lb. of coal was increased, and the temperature of the escaping gases fell to 525° . The flame penetrated freely between the spheres for a distance of 8 or 10 feet from the bridge, and three fourths of the whole evaporation probably took place within this distance. The spheres in the slabs at the back of the boiler were generally covered with a light coating of soot, which was swept off every week, all

the spheres being within easy reach for this purpose; soot never formed however upon the spheres near the fire. The water level was very steadily maintained within a small range of oscillation; and as the feed water entered the boiler at the back, there could be no doubt, when it stood at its proper height in the glass gauge in front, that its level was properly maintained throughout the whole length of the boiler. A small cock tapped into one of the steam spheres a short distance above the water level showed damp steam, indicating a vigorous circulation of the water below; but in the engine room the steam blown from the cylinder cock was quite dry, showing the value of the superheating surface formed by the upper or steam spheres of the boiler.

In reference to the mode of making the castings of the boiler and forming the joints, the system pursued in the foundry is such that, with green sand cores, the units are moulded with about the rapidity and economy of plate moulding. The cores are well rammed on the eight prints upon which they rest in the sand, and there is no chance of their being displaced in pouring the metal or otherwise, except by a force sufficient to break them in pieces. The two halves of the moulding boxes are drawn apart in such a manner as to prevent any chance of breaking down the sand, and little or no sleeing is required. Each casting is critically inspected; but as the moulders are not paid for imperfect castings, very few are made.

The joints are faced up by special and powerful machinery. The spheres are 9 inches from centre to centre in the same unit, and the facing machines not only preserve that distance exactly between the openings on the same side of each unit, but also face the joints on the opposite sides of the unit to the precise gauge of $8\frac{3}{4}$ inches apart. Each machine has two headstocks, with eight spindles and rose cutters in each headstock; and the castings being securely held in a clamp are faced in pairs, a roughing cut being taken on the eight joints of one casting, while a finishing cut is going on upon the joints of the other. Twenty-five tons of castings pass under the roughing cutters before they require grinding; and

100 tons of units are completely faced by the finishing cutters before these require to be re-ground. By a special adjustment the finishing cutters may be set up in their spindles to the one-thousandth part of an inch, whenever, from the dulling of the cutting edges, the distance between the opposite joints of the units is found to exceed the length of the standard gauge by that quantity.

Out of a number of castings, any two exactly correspond, and when placed together the bearing surface at each joint is $\frac{3}{16}$ ths inch wide all round, and it is finished with a truth not inferior to that of a good slide-valve face. If a sheet of oiled paper be placed upon a smooth board and two units be placed upon it, one above the other, they may be filled with water without any perceptible leakage at the joints even after the lapse of a week.

In conclusion it is considered by the writer that the boiler now described possesses several important advantages. It is believed to be absolutely secure from explosion, and, so far as experience has gone, free from any liability to choke with scale. It is durable, easily taken apart and put together, and may be erected in almost any form adapted to the space in which it is to be placed. The parts are very portable, and may be taken through any opening where a boy can pass. Any part of the boiler may be readily renewed if necessary; and an existing boiler may at any time be readily enlarged, and that to an indefinite extent, by adding to the number of slabs, either at the sides or at the back. The economy of the boiler in first cost is obvious; and with proper proportions between the firegrate and the heating surface, as high an evaporative efficiency may be obtained as with most other constructions of boilers. The quantity of water contained in the boiler being comparatively small, steam may be raised with a small quantity of fuel and in a short space of time. Water may be left standing in the boiler for almost any length of time without injury. Every part of the boiler is at all times under ready observation without disturbing the connections; and the outsides of the spheres may be easily swept. The setting of the boiler is such that the steam may

be dried to any extent desired in the spheres themselves, without any other provision for superheating. It is thought that this boiler especially meets the present increasing tendency to use high pressure steam, and that the description now given will therefore prove interesting to this Institution.

Mr. COLBURN exhibited a set of spheres from the boiler, forming one complete slab, and also specimens of the steam and feed connections at top and bottom of the boiler, together with one of the spheres that had been broken open after eight months' constant work, to show the state of the interior surface and its complete freedom from corrosion or scale. He showed also specimens of the thin small scales blown out from the boiler, which was all the deposit there was to be found; and of the thick hard deposit chipped off from the interior of an ordinary Lancashire boiler using the same water.

The CHAIRMAN had seen the new boiler at work in Manchester, and considered it an important step towards the use of steam at a higher pressure than could at present be adopted. It was much more simple in construction than would at first sight appear; and with the facilities now possessed for multiplying parts of the same size and shape, he did not see any reason why it should not be put together easily and at a very small cost. He enquired what was the temperature of the waste heat passing off from the new boiler into the chimney, as that was an important criterion of the economy of a boiler.

Mr. COLBURN had not had an opportunity of ascertaining the temperature of the waste heat from this boiler, but by increasing the length of it the heat at the chimney end could be reduced as low as desired. At Messrs. Hetherington's works in Manchester there were originally two ordinary Lancashire boilers, but when

the new boiler was added only one of these was worked with it; the waste heat from both however passed into the same chimney, so that there was no opportunity of trying the temperature from the new boiler alone. The boiler at those works was in the first instance longer, but was afterwards shortened by the removal of some of the spheres at the further end. The water was left in the boiler during the night, and in the morning was still at a temperature of 212° Fahr., owing to the heat retained in the mass of brickwork surrounding the boiler; and from this point steam was got up in 10 or 12 minutes to a pressure of 50 lbs. per square inch above the atmosphere. There was great convenience for readily inspecting the boiler by means of the manhole doors, by which access was obtained at once to the whole boiler, with a clear sight through the entire length, and a man could get in and sweep the whole of the spheres clean without any difficulty at all.

As regarded the freedom of cast iron from any tendency to corrosion, when used as the material for steam boilers or for other purposes where it was exposed to a high temperature, he was informed by Mr. Jaffrey of Hartlepool that he had employed cast iron for superheaters with success, and four cast iron superheaters fitted on board steam colliers showed no sign of corrosion when examined in October last, after four years of almost constant work; the pipes when cleaned looked almost like new castings, almost as clean as when first put in.

Mr. G. A. EVERITT thought the new boiler would be very useful in connection with puddling or heating furnaces, where the waste heat from the furnace was made use of for generating steam; it appeared very suitable for such applications on account of its safety and the small space it occupied, and he enquired whether it had been employed for that purpose.

Mr. T. L. LUDERS replied that he was now about to put up one of the boilers to be heated by the waste heat from three puddling furnaces: there were eight sections of spheres in the boiler, and the heat from the furnaces was made to circulate completely through the set of spheres in each section by means of firebrick partitions, making the passage to the chimney the longest possible. The boiler was

carried entirely upon a pair of cast iron columns in front and the brickwork upon which it rested at the back, independent of the brickwork of the furnaces ; so that the latter could be pulled down for repairs without disturbing the boiler, while the boiler also was completely accessible at all times without requiring any part of the brickwork of the furnaces to be removed. The boiler had thus the important advantage for such an application that it could be placed over the furnaces without occupying any of the room of the forge or hindering the repairs of the furnaces. By means of suitable dampers the amount of heat allowed to pass through the boiler could be regulated as desired, according to the generation of steam required ; and the heat from any one of the furnaces could be conveyed away direct into the chimney, without passing at all through the boiler, if only a smaller quantity of steam were wanted to be raised.

In the earlier boilers that he had made, the spheres were set at an inclination of about 15° , but in the most recent ones they were placed at 45° , which was found to answer the best, because it gave a complete drainage of every sphere in the boiler into the bottom blow-off pipe ; while the point of taking off the steam being the highest in the boiler was the furthest from the water line. Near the level of the water line the steam would of course be damp from contact with the water ; but the surface of the spheres above the water line being exposed to a high temperature, say 650° Fahr., the steam became moderately superheated to a temperature due to that exposure before passing off from the top of the boiler, and it was then found hot enough to continue dry after passing through 40 feet of unprotected pipe to a low pressure engine worked by it.

The CHAIRMAN enquired what was the cost per horse power of the new boiler.

Mr. T. L. LUDERS replied that the cost of the boiler was £15 per ton at the works in Manchester, and the power was reckoned at about 3 horse power per ton, making the cost per horse power about £5. In reference to the temperature of the waste heat escaping from the boiler, he had found the waste heat from an ordinary Lancashire boiler doing rather less work than the new boiler was from 580° to

600°: while the waste heat from the new boiler was from 500° to 600°. The extent of variation in the latter case was accounted for by the quantity of coal consumed per square foot of grate per hour, amounting to 21 lbs. of coal; and it was evident that as the consumption of coal was increased, and the rapidity of the draught also increased by opening the chimney damper in order to burn the larger quantity of coal, the heat escaping into the chimney must also be proportionately increased. The Lancashire boiler experimented upon was one with a moderate draught, but having a larger firegrate area and burning its fuel much slower than 21 lbs. per square foot of grate per hour. That would give a much higher evaporative efficiency, and the temperature of the waste heat escaping to the chimney would be lower, owing to the draught being less keen and the heat being more fully taken up by the boiler.

Mr. C. W. SIEMENS remarked that certainly the new form of boiler was emphatically a strong form, inasmuch as a sphere of 1 foot diameter had as much strength to resist internal pressure as a pipe of half that diameter, the thickness of metal being the same. Moreover the spherical form was a very good form in cast iron he thought for a boiler, because it yielded to expansion equally in all directions: cast iron readily gave way when exposed to unequal heat, and in ordinary plate boilers the wrought iron often gave way in consequence of unequal expansion in different parts. But he did not expect that the new boiler would give way by any part being overheated in comparison with the rest, because every portion of a hollow sphere could yield freely to local expansion by heat. He had at various times used cast iron heated to a high temperature, and had found that, to make it stand, the question of expansion had above all things to be attended to. The heating surface in the boiler appeared likely to be highly efficient, because the flame was continually broken in its passage over the interrupted surface presented by the balls, instead of passing through a long plain internal tube in a continuous unbroken current, as in an ordinary boiler, where the interior mass of the flame came comparatively little in contact with the boiler surface. He therefore hoped the

new boiler would receive a fair trial at the hands of those using steam boilers. The several balls composing the boiler must require to fit together with very great nicety in order to prevent leakage at the joints, and he enquired whether they had ever been found to leak at the joints; and whether they were not found to give way at the joints after working for a considerable time, in consequence of the alternate heating and cooling, since cast iron by being heated and cooled very often was known to become permanently enlarged.

Mr. T. L. LUDERS replied that there had not at present been a very long experience with the new boiler of which to speak, but so far as the tightness of the joints had hitherto been tested by time their durability had been surprising, as they had never shown the slightest sign of a leak. Very much depended in practice upon the facing of the joints being truly accurate machine work, and this was ensured by the mode of facing the two sets of cutters of the machine in which the joints were faced simultaneously on opposite sides: while the cutters were all revolving, firmly wedged in their holders in their permanent working position, but of soft steel not yet hardened, a facing tool sharpened at both edges and made by a standard gauge to correspond to the exact distance between the joints was passed transversely across the machine, grinding the cutters to the exact length required for facing the joints accurately to the proper length. The joints then fitted together perfectly without the slightest force being used, and when the bolt was passed through to hold them together they were quite steam-tight under any pressure of steam at which the boiler would be worked. There were 1800 balls in the last boiler made for Messrs. Hetherington's works, and not a single leakage had been detected in all that number. The result of two years' experience with the boilers at Messrs. Sellers' machine works in Philadelphia was that there had been no leakage; while at the same time the boilers had been so economical that more than 100 tons of the ball castings for new boilers had been ordered from England for works at the same place, and would be put up in the place of good boilers at present in use there. The new boilers had now worked in America for

eighteen months with only once being opened at the end of eight months for the purpose of clearing the balls if that should be necessary, and then only a little scale and mud was raked out of the bottom row of balls; and during the ten months that had elapsed since that time they had not been opened at all. The experience in all cases had been the same as to the absence of scale or deposit, even after a long time of working.

With regard to the manner in which the new boilers stood the test of rust, one of them had been exposed for four years to the most severe test for rust that was likely to be met with. The boiler was 70 feet long and 1 foot high, in a greenhouse, where it was fired during only about three months in each year, and the remaining time it was allowed to stand full of water, which was no doubt the severest test it could be put to for rust. With plate boilers under such circumstances the plates were generally found to rust very rapidly. But this had not been the case with the new boiler: although the joints had been made four years they still continued perfectly water-tight, notwithstanding the fact that at the time the boiler was made there was no machinery for facing the balls, and the joints were merely planed and ground up with emery. The present machine-made joints were all found to remain perfectly tight.

The reason for setting the boiler in an inclined position instead of level, independent of the advantage of the balls emptying themselves completely when set inclined, was the fact that, in consequence of the difference of temperature between the water space and the steam space at the time of raising steam from cold water, the boiler could not be used if it were brought down level. For it was found by experiment that when the lines of balls were set horizontal a conflict resulted at the water line between the parts above and those below, in consequence of the difference of temperature, the cooler portions below the water line pulling against the more expanded parts above; and the strain produced would so rack the joints as to render the boiler a failure. This conflict disappeared however as soon as the lines of balls were set at the inclination of 45° that had now been adopted, as there was

then no sudden change from hot to cool between any two adjacent lines of balls; and though all the tie bolts crossed the water line at different portions of their length, and thereby became unequally expanded by the hot steam space, yet the change was gradual from one bolt to the next, and no two adjacent bolts pulled against each other; and the expansion of the whole boiler thus took place without throwing a strain upon any part.

The feed pipe was connected to the bottom corner of the boiler in this inclined position, and the steam pipe was taken off from the top corner with a long bend, in order to allow perfect freedom for the expansion of the boiler, the effect of which would be all concentrated at that point. In the first boilers the steam connecting pipe was a cast iron transverse pipe with straight branches on the underside, to which the sections of the boiler were directly attached, forming a rigid connection at each section. But it was then found that the several connections in this case were so difficult to make in the first instance, from the difficulty of setting all the sections of the boiler in their places with sufficient accuracy, and when set the irregular expansion of the different sections was so apparent, from the unequal heat of the fire at different parts before the steam was fully up, that there was a pushing and pulling action at the connecting pipe which gave a great deal of trouble by breaking the castings, the pipe being stronger than the castings. This was however quite obviated by the present curved wrought iron pipes, forming the connections from the castings to the steam pipe, as seen in the specimen exhibited; these were screwed into sockets in every alternate casting, and allowed perfect freedom for the expansion of any section of the boiler, independent of the rest, so that there was now not the slightest trouble, nor any strain that could produce leakage at any of the joints.

The inclination of the balls at 45° gave the greatest length of water line, since the water line was then the diagonal of a square. It also allowed the steam to escape with great readiness from the water, as fast as it was generated, passing off without meeting or obstructing the water that was rushing in through another opening to take its place; and in consequence of this advantage the water

level seldom oscillated more than $\frac{1}{2}$ inch: indeed that amount of variation in level was considered a great disturbance in the boiler.

Mr. F. W. WEBB enquired whether the joints of the balls were put together simply metal and metal, or whether any red lead or oil was used for making them.

Mr. T. L. LUDERS replied that the joints were put together metal and metal, as in the specimens exhibited, just as they were left faced by the cutters of the machine, without any subsequent grinding, and without any oil or red lead or any other material in the joint. The cutting machine was made wide enough to take in one of the four-ball castings of the boiler, having four pairs of the revolving cutters, so as to cut all the four joints on each side of the casting simultaneously. The time occupied by the operation was about 8 minutes for each casting, from the time of putting the rough casting into the machine with the cutters drawn back, until it came out with all the eight joints finished ready for being bolted together at once in a boiler without any further preparation of the surface of the joints. The revolving cutters were advanced by a pair of eccentrics having $\frac{5}{8}$ inch throw, and were fed up by hand at first to bring them up to the surface of the casting, after which the self-acting feed motion of the machine was put in operation. The cutters came in contact with the metal when the eccentrics were at half stroke, having the quickest motion for advancing the cutters; and the forward motion then gradually diminished until the full throw was reached, at which time the speed of the revolving cutters was also diminished, so that at the last the tools gave nothing but a scraping finish to the face of the metal at a slow speed.

Mr. C. F. BEYER remarked that the new boiler was composed of a great number of separate parts put together, and at first sight it would appear that there must be considerable difficulty in making so great a number of pieces go together with sufficient accuracy to prevent leakage at the joints. He had however seen the machinery that was used for facing the joints, and thought it admirably adapted for the purpose; the accuracy with which it did the work was certainly very great, and there appeared no reason why the joints shaped by that machinery should not be water-tight and

steam-tight under all pressures at which the boiler would work. The construction and working of the machinery were moreover such that the shaping of all the joints in the several castings of a boiler would form but a small item in the total cost of the boiler.

Mr. E. REYNOLDS enquired what became of the scale that was formed in the boiler during the week's work: whether it remained in the boiler until blown out at the end of the week, or whether any of it got carried over with the steam into the engine. He knew a pair of 50 inch cylinder engines upon the pistons of which an accumulation of from $\frac{1}{2}$ inch to $\frac{3}{4}$ inch thickness of scale was frequently found.

Mr. T. L. LUDERS replied that the boiler was not blown out at all except after working hours at the end of each week. From the result of observation he supposed that all the scale formed during the week's work became deposited on the surfaces of the balls in a layer about as thin as an eggshell, just in the same manner as on the surfaces of an ordinary plate boiler, so that the whole of the inside of the boiler became coated throughout the water space with a thin scale. In blowing out the boiler at the end of the week, the brickwork having been maintained during the week at a temperature of about 600° on the inside, it was only allowed to cool till the red heat had gone out of the bricks in the bridge wall, and then the boiler was blown out. But as there was still a temperature of as much as 500° in the brickwork, the whole mass of the empty boiler became very hot, and the scale either became altogether detached then by the expansion of the metal, or else the loosening of the scale was completed subsequently he presumed, when the boiler became cold, the contraction of the balls in cooling having the effect of crushing down the thin and friable scale in all directions and causing it to shell off from the metal in small pieces, or at least to become completely loosened from the metal, so that when the water was next put into the boiler it could get behind the scale and throw it off. The loose scale would then lie in small pieces at the bottom of the balls until the end of the week; and the scale formed in one week was therefore he imagined blown out at the end of the week following. The constant repetition of this process was he thought

the reason of the balls being kept quite clear of scale. As to any scale being found in the steam pipes or cylinder of the engine, such an occurrence had never been met with in the working of any of the new boilers; but he thought it probable that, if the boiler were worked too long without blowing out, the balls would become choked with mud. He had however known every one of these boilers that had been put up at present, and had never found any incrustation larger than the small pieces of scale now exhibited, scarcely thicker than eggshells. This specimen was only collected by letting the water run out of the boiler slowly, and then opening the lowest ball and collecting the pieces of scale from it by hand, so that there was no doubt that was a fair sample of the weekly production of the boiler. This scale presented a great contrast to the other specimen exhibited of the scale obtained from an ordinary Lancashire boiler working with the same water, which was the usual description of scale found in all ordinary plate boilers, about $\frac{1}{8}$ inch thick and requiring to be broken from the inside of the boiler by blows of a hammer.

Mr. J. M. HETHERINGTON said they had now had the new boiler in use at their works in Manchester for the last eighteen months, during which time they had made many experiments to test it in a variety of ways with most satisfactory results. The joints of the balls had been found entirely satisfactory, for he did not know of a single instance in which the joints in a good casting had given way. The castings as they came from the machine that had been described had all the joints faced so perfectly true that to put any cement or tallow or oil on them appeared to make them worse than the clean surface of metal to metal; and they remained completely steam-tight and water-tight under the expansion and contraction of the boiler. At the time of putting up the boiler at their works, when all the sections were screwed up and fixed in their places and the fire first lighted, he believed there was not a single leaking joint in the whole boiler.

The temperature of the waste heat escaping into the chimney from the new boiler he believed to be about the same as from an ordinary Lancashire boiler, between 500° and 600° Fahr.; but in the new boiler the whole of the heating surface being in such close

proximity to the fire was more efficient than in ordinary boilers, where the further end of the boiler was sometimes as much as 90 feet distant from the fire, so that much of the surface could receive but little heat. The draught was much keener in the new boiler than in an ordinary one, and they had had some difficulty at first in so far checking it as to burn only the same amount of coal per square foot of grate as in ordinary boilers; but this difficulty had now been overcome. No doubt a reduction in the temperature of the waste heat would be advantageous, and it could be obtained by increasing the area of firegrate, so as to burn the coal more slowly and thereby give time for a little more of the heat from the fire to be retained by the boiler.

The practical result obtained with the new boiler at their works had been that it had effected a saving of 20 per cent. on the total cost of coal for raising steam: and in consequence of the capacity of the boiler for generating a high pressure of steam with perfect safety, they were now about to make use of steam of 100 lbs. per square inch pressure, or 120 lbs. in the boiler, by adding a high pressure cylinder to exhaust into the cylinder of their present condensing engine; and they intended to adhere to the cast iron boiler for the future, in place of the ordinary wrought iron boilers.

Mr. I. SMITH enquired whether the water used in the boilers at Manchester contained sulphate of lime or carbonate of lime. He could understand sulphate of lime being deposited as a scale in the new boilers and being blown out at the end of the week, as had been described: but in the neighbourhood of Birmingham the water contained besides sulphate of lime a large quantity of carbonate of lime, which was deposited in boilers in the form of mud, and where the firing was below the boiler frequently caused damage to the plates by overheating. Hence if this water were used in the new boiler, unless there were a daily blowing out of the boiler, he thought great damage would result to the lower line of balls, as there appeared no reason why the new boiler should be exempt from the same accumulation of mud which took place in ordinary boilers using such water.

Mr. T. L. LUDERS replied that he had not any analysis of the water that had been used in the new boilers, and did not know what compound of lime it contained : the specimens of deposit now exhibited had the appearance of sulphate of lime, but he could not tell what would be the effect on the boiler if any deposit were ever formed that was elastic enough and sufficiently firmly fixed not to be cracked off the metal by the contraction of the balls in cooling. The expanding scraping tool described in the paper had been constructed to scrape out the scale in such cases if they ever arose ; but no instance of the kind had yet been met with in the working of the new boilers, but in every case the result had been the same as regarded the absence of deposit, in America, in London, and also in Manchester ; and he therefore thought there was reason to hope it would be the same in a great many other cases. In Philadelphia one of the boilers had now been working regularly for nearly two years, during which time it had only been opened once ; and another boiler there was not opened for a period of eight months, and at the end of that time the whole collection of deposit that was left from the weekly blowing out was cleared away in a few hours by simply scraping out the lower line of balls with the tool provided for the purpose. The broken casting that was exhibited from the boiler in Manchester had never been opened until broken by the hammer after eight months' constant work : and the interior surface was exactly in the same state as when broken open, showing complete freedom from scale in all parts, though the boiler had been as much exposed to the liability of forming scale as any boiler was ever likely to be.

The CHAIRMAN proposed a vote of thanks to Mr. Colburn for his paper, which was passed.

The following paper was then read :—

ON THE
DISTRIBUTION OF WEIGHT
ON THE AXLES OF LOCOMOTIVES.

By MR. JOHN ROBINSON, OF MANCHESTER.

Amongst the causes affecting the steadiness of locomotive engines in motion, and thereby also the general steadiness of trains on railways, the Distribution of Weight upon the various Axles, it is believed, has not received the amount of consideration which the subject deserves. There are numerous circumstances which must necessarily be taken into consideration for determining the position of the axles of an engine relatively to its general mass. The most important object is to obtain sufficient weight upon the driving wheels, whether single or coupled, for giving the amount of adhesion necessary to draw the load and ascend the gradients for which the engine is to be adapted: and another consideration of great importance in fixing the position of the axles is the number and sharpness of the curves on the road along which the engine has to pass. These two conditions naturally influence the distance between the several axles of the engine, especially the extreme ones, the distance between which is technically called the "wheel base."

These two main conditions, of the weight on the driving wheels and the nature of the curves on the line, being fixed, the question arises how best to distribute the weight of the engine on its axles. Some idea of the difficulties surrounding the solution of this question may be obtained by a glance at the accompanying diagrams, Figs. 1 to 15, Plates 24 to 28, which represent some of the multitudinous arrangements that have been adopted in order to meet the different requirements of railway companies. Locomotives in general may be divided for the present purpose into the fifteen classes illustrated by the diagrams, each of which it will be seen presents different obstacles to obtaining a proper distribution of

weight upon the axles. The figures given as the weights at the several axles are taken with an ordinary working quantity of water and fuel in the boiler and firebox, and in the tank engines with the tanks fully loaded.

Fig. 1, Plate 24. Four-wheeled engines having Inside cylinders are generally used for mineral and coal lines, and for forming trains at stations. It will be seen by the diagram that a very large amount of weight here comes upon the hind axle, in consequence of the overhanging firebox; and this can only be alleviated by making the boiler unusually long in proportion to the firegrate and flue area, as shown by the dotted lines. The actual weights upon the axles of such an engine in working order, with cylinders 14 ins. diameter by 20 ins. stroke and wheels 3 ft. 9 ins. diameter, have been ascertained by the weighing machine to be

Leading axle	6.00 tons
Hind axle	12.50 „
Total adhesion weight . .	<u>18.50</u> „

And with the longer boiler shown by the dotted lines the weights are

Leading axle	7.38 tons
Hind axle	11.80 „
Total adhesion weight . .	<u>19.18</u> „

The weight required for maximum adhesion in this engine is 18.49 tons; that is the weight required for making use of the maximum power of the engine, under the most favourable circumstances when the adhesion friction is at its maximum amount of 1.5th of the load, and the mean effective steam pressure in the cylinders throughout the stroke being taken at 95 lbs. per square inch in starting the train.

Fig. 2, Plate 24. The unequal distribution of weight upon the axles of inside-cylinder four-wheeled engines, as shown in Fig. 1, may to some extent be avoided by placing the cylinders outside the frames, as in Fig. 2; for in this case the increased weight forward of the cylinders and their attachments, and the possibility of getting the straight driving axle much nearer to the firebox than a crank

axle could be placed, tend more nearly to equalise the weight upon the two axles. On the other hand a less substantial engine is thus obtained, especially where coupled; since the coupling rod passing inside the connecting rod and the slide bars renders it difficult to secure a good attachment to the frames. The actual weights ascertained upon the axles of such an engine in working order, with cylinders 15 ins. diameter by 24 ins. stroke and wheels 4 ft. 6 ins. diameter, have been

Leading axle	10·00 tons
Hind axle	11·25 „
	<hr/>
Total adhesion weight . .	<u>21·25</u> „

the weight required for adhesion being 21·25 tons.

In Four-wheeled Tank engines, in which the supply of water and fuel is carried by the engine itself, by arranging the position of the water tank so as to keep its own weight, as well as that of the water it contains, well forward, the leading axle may be made to bear a larger proportion of the additional weight than the hind axle, whether the cylinders be placed inside or outside the frames. This is however counterbalanced by the necessity for lengthening the footplate and fencing it at the back, for the purpose of carrying the fuel, thereby increasing the weight overhanging the hind axle. The actual weights obtained in such an engine, with inside cylinders 13 ins. diameter by 18 ins. stroke and wheels 3 ft. 9 ins. diameter coupled, have been

Leading axle	7·45 tons
Hind axle	14·95 „
	<hr/>
Total adhesion weight . .	<u>22·40</u> „

the weight required for adhesion being 14·37 tons.

Fig. 3, Plate 24, and Fig. 4, Plate 25. The next class of engine is that which has hitherto been considered the ordinary type of Passenger engine, having six wheels all uncoupled, the middle or driving axle being placed under the cylindrical part of the boiler in front of the firebox, the leading axle behind the cylinders, and the hind axle behind the firebox. In arranging an engine of this description, it is usually sought to have the greatest weight upon

the middle axle, then a less weight upon the leading, and a still less weight upon the hind axle; but to have these weights not so disproportionate as that it shall be impossible to vary the weight upon the middle axle within a moderate range by a corresponding adjustment of that upon the leading axle. In this respect the inside-cylinder arrangement presents an advantage over that with outside cylinders, since the leading axle in inside-cylinder engines can be placed much nearer to the smokebox and the weight upon it thereby diminished, on account of the cylinders not interfering with the leading wheels as in outside-cylinder engines. The connecting rod also is then capable of being made longer, in consequence of the increased distance from the smokebox at which the middle axle may be placed without throwing too much weight upon the leading axle, which in engines with short boilers is often a matter of considerable importance. It may be remarked that the arrangement of uncoupled engines with all the axles under the cylindrical part of the boiler is now almost discarded, at least in this country; since they are found to be so unsteady, in consequence of the overhanging weight of the firebox, that high speeds can not safely be accomplished with them.

Fig. 3, Plate 24, shows a good distribution of the weight in an Inside-cylinder Passenger engine, having cylinders 15 ins. diameter by 20 ins. stroke, middle wheels 5 ft. 6 ins. diameter, and leading and hind wheels 3 ft. 6 ins. diameter; the total weight being 23·06 tons, distributed as follows:—

Leading axle	8·16 tons
Middle axle	10·10 tons
Hind axle	4·80 „
Total adhesion weight . .	<u>10·10 „</u>

the weight required for adhesion being 14·48 tons.

Fig. 4, Plate 25, is an example of a favourable distribution in an Outside-cylinder Passenger engine, the “Lady of the Lake” of the London and North Western Railway, shown at the International Exhibition of 1862. With cylinders 16 ins. diameter by 24 ins. stroke, middle wheels 7 ft. 7½ ins. diameter, leading and hind wheels 3 ft. 8 ins. diameter, the distribution of the weight is

Leading axle	9.40 tons
Middle axle	11.50 tons
Hind axle	6.10 „

Total adhesion weight . . . 11.50 „

the weight required for adhesion being 14.24 tons.

Fig. 5, Plate 25. The construction of uncoupled engines with tanks is not of very frequent occurrence. As however many such engines were made formerly, the distribution of one is given with the tank placed under the footplate behind the firebox; inside cylinders 15 ins. diameter by 20 ins. stroke, middle wheels 5 ft. 6 ins. diameter, leading and hind wheels 3 ft. 6 ins. diameter. The distribution was

Leading axle	7.35 tons
Middle axle	10.25 tons
Hind axle	6.95 „

Total adhesion weight . . . 10.25 „

the weight required for adhesion being 14.48 tons. The placing of a tank underneath the cylindrical portion of the boiler in an outside-cylinder uncoupled engine simply tends to increase the weight upon the leading axle, already too heavily loaded, and has not been extensively adopted within the range of the writer's observation.

During the past few years there has existed in this country a growing tendency to adopt engines with Four Coupled wheels for the passenger trains on the great trunk lines, and for the mixed trains on shorter and branch railways: in the former case in consequence of the great number of passenger carriages required in many of the trains; and in the latter owing to the desirability of having engines of sufficient power to work trains composed partly of passengers and partly of goods. In most cases such engines have been built with small leading wheels and with the middle and hind wheels coupled, under the impression that it is safer to run at high speeds with wheels of small diameter in front than if their size were such as is usually employed when coupled for driving. In regard to the best distribution of weight upon the axles of such

engines, it is evident that the difficulty is, whether in the case of inside or outside-cylinder engines, to get a fair proportion of weight upon the hind wheels so as to justify their being coupled to the middle wheels, assuming the position of the hind axle to be behind the firebox: and in order to show that this question is not easy of solution, the following instances are given of the distribution of weight upon the axles of such engines.

Fig. 6, Plate 25. Coupled Passenger engine with Outside cylinders 16 ins. diameter by 22 ins. stroke, middle and hind wheels coupled 5 ft. 7 ins. diameter, leading wheels 3 ft. 7 ins. diameter. Total weight 31·60 tons, of which the distribution is

Leading axle	10·80 tons
Middle axle	11·85 tons
Hind axle	8·95 „
Total adhesion weight . .	<u>20·80 „</u>

the weight required for adhesion being 17·83 tons. In this engine a heavy cast iron block was added, forming the footplate, in order to obtain the above distribution of the weight.

Fig. 7, Plate 26. In the case of engines with Inside cylinders it is more easy to load the hind wheels sufficiently to prevent an exaggerated load upon the leading wheels; because the latter being placed more forward in the engine than is usually possible with outside cylinders, the weight on them is diminished, and when the middle axle is relieved from unnecessary weight by adjustment of the springs, a greater proportion is taken by the hind wheels than would be the case if the leading wheels were nearer the middle wheels. In such an engine with cylinders 15 ins. diameter by 20 ins. stroke, middle and hind wheels 5 ft. 6 ins. diameter, leading wheels 3 ft. 6 ins. diameter, total weight 25·80 tons, the distribution has been

Leading axle	8·39 tons
Middle axle	10·00 tons
Hind axle	7·41 „
Total adhesion weight . .	<u>17·41 „</u>

the weight required for adhesion being 14·48 tons. In this engine extra weighting of the footplate as in the previous instance was not required.

Fig. 8, Plate 26. Another example of this class of engine is that in which the sloping of the bottom of the firebox upwards from front to back allows of the hind axle being placed under the ashpan, whereby it carries a much larger share of the weight of the engine than would otherwise be possible. Two instances of this kind are given, because the distribution seems a very advantageous one, and has been obtained without the addition of useless weight to the engine. An engine with cylinders 17 ins. diameter by 22 ins. stroke, middle and hind wheels 6 ft. 6 ins. diameter, leading wheels 4 ft. 0 ins. diameter, had the following distribution :—

Leading axle	9·36 tons
Middle axle	11·57 tons
Hind axle	9·71 „
Total adhesion weight . .	<u>21·28</u> „

the weight required for adhesion being 17·29 tons. In another engine, with the same size of cylinders and wheels, the distribution was

Leading axle	9·56 tons
Middle axle	11·01 tons
Hind axle	9·80 „
Total adhesion weight . .	<u>20·81</u> „

the weight required for adhesion being 17·29 tons.

When it is desired, as is not unfrequently the case, to construct such engines for carrying their own supply of fuel and water, it is easy so to arrange the position of the tanks as to get an excellent distribution of weight upon the wheels; and if the tanks be conveniently placed on the side frames pretty equally over the coupled axles, the loading and unloading of the coupled wheels in moderately equal proportions is secured, when the tanks are first filled and afterwards gradually emptied by the supply to the boilers: whereas, when the tank is placed under the footplate, the hind axle has a much larger proportion of the gross weight of the engine to carry when the tank is full than when it is empty. The weights obtained in an engine of this class, with cylinders 15 ins. diameter by 20 ins. stroke, middle and hind wheels 5 ft. 0 ins. diameter, leading wheels 3 ft. 6 ins. diameter, have been

Leading axle	8.50 tons
Middle axle	10.13 tons
Hind axle	9.51 „
Total adhesion weight	<u>19.64 „</u>

the weight required for adhesion being 15.94 tons.

Fig. 9, Plate 26. One of the most generally useful classes of engine for the common purposes of railways is the six-wheeled engine having the Four front wheels Coupled, since it can be used for ordinary goods trains, or for heavy passenger trains when not run at too great a speed. The advantage of such an arrangement of engine, if made with Inside cylinders, is that nearly the whole weight of the engine may be conveniently distributed upon the four coupled wheels, leaving but a small proportion for the hind wheels, which in this case do little more than serve to avoid the disadvantages of an overhanging firebox. Where the load to be drawn permits the use of such an engine, the additional wear and tear necessarily following upon the adoption of six coupled wheels is obviated. The following is a good example of distribution of weight on the axles of an engine of this class, with inside cylinders 16 ins. diameter by 22 ins. stroke, leading and middle wheels 5 ft. 0 ins. diameter, hind wheels 3 ft. 6 ins. diameter:—

Leading axle	9.77 tons
Middle axle	10.27 „
Hind axle	4.42 tons
Total adhesion weight	<u>20.04 „</u>

the weight required for adhesion being 19.91 tons.

Fig. 10, Plate 27. It is evident that by changing the relative positions of the leading and middle axles, the distribution of the weight in the last example may be varied as required without danger of getting a disproportionate length of connecting rod. But where such engines are to be constructed with Outside cylinders, a difficulty as to distribution immediately arises, since the large diameter of the front wheels renders it necessary that the leading axle be placed at a considerable distance behind the cylinders, and thus a much larger proportion of the weight of the

engine is thrown upon the leading wheels than is either necessary or desirable. The distribution obtained in an engine with outside cylinders 15 ins. diameter by 22 ins. stroke, leading and middle wheels 4 ft. 6 ins. diameter, has been

Leading axle	10.00 tons
Middle axle	11.07 „
Hind axle	4.62 tons
<hr/>	
Total adhesion weight . . .	<u>21.07</u> „

the weight required for adhesion being 19.47 tons.

Engines of this class are sometimes required to carry their own supply of water and fuel, in which case it seems most desirable to place the water tank on the top of the boiler, so as to increase the load proportionately on the coupled wheels, and let the hind wheels carry the increased weight involved in the fuel boxes and fuel. This arrangement secures an equal increase and decrease in the proportion of the weight carried by the coupled wheels, as the tank is filled and emptied; and avoids the objection that arises in placing the tank under the footplate, from the great disproportion of the load upon the hind wheels when they carry nearly the whole weight of the water, fuel, and tanks. The distribution of weight in a "saddle" tank engine, having Inside cylinders 14 ins. diameter by 20 ins. stroke, leading and middle wheels 4 ft. 9 ins. diameter, is

Leading axle	9.60 tons
Middle axle	11.24 „
Hind axle	5.07 tons
<hr/>	
Total adhesion weight . . .	<u>20.84</u> „

the weight required for adhesion being 14.59 tons. Should it be desired to add tanks to engines of this class with Outside cylinders, it is clear that a certain amount of the superfluous weight upon the leading wheels might be counterbalanced by placing the tank under the footplate; but the disadvantage would still continue of disproportionately loaded axles, according as there was a greater or less quantity of water in the tank.

Fig. 11, Plate 27. The next class of engines to be referred to is that used for heavy goods traffic with all Six wheels Coupled.

Such engines constructed with Inside cylinders are very common, though a good distribution of weight upon their axles is not easy, since the hind axle when placed behind the firebox has naturally but a comparatively small proportion of the weight of the engine to carry; and if, in order to obviate this disadvantage, it is sought to move the middle axle nearer to the cylinders, the due length of the connecting rod is sacrificed, unless the length of the boiler be increased, giving a corresponding increase in the wheel base of the engine, which in railways having sharp curves is by no means desirable, especially in an engine having all the wheels coupled. A favourable distribution of weight in an engine of this kind with inside cylinders, 16 ins. diameter by 24 ins. stroke, and wheels 5 ft. $1\frac{1}{2}$ in. diameter, is

Leading axle	10·60 tons
Middle axle	10·90 „
Hind axle	7·25 „
Total adhesion weight . .	<u>28·75</u> „

the weight required for adhesion being 21·18 tons, and the wheel base 16 ft. 3 ins.

Fig. 12, Plate 27. A large number of engines with Six Coupled wheels have been built with all their axles underneath the cylindrical part of the boiler, so as to attain the double object of a short wheel base and a more equal distribution of weight upon the axles. With such an arrangement the following have been the results in an engine with inside cylinders 18 ins. diameter by 24 ins. stroke, and wheels 5 ft. 0 ins. diameter:—

Leading axle	7·70 tons
Middle axle	10·35 „
Hind axle	9·95 „
Total adhesion weight . .	<u>28·00</u> „

the weight required for adhesion being 27·45 tons, and the wheel base 12 ft. 2 ins. The advantage so obtained of a short wheel base is however counterbalanced to a considerable extent by the instability created by the overhanging firebox, which, when the firebox is large, is a matter of serious importance.

Fig. 13, Plate 28. As a mean between the extremes of the last two examples stands the Six-wheeled Goods engine with long firebox having the grate sloping upwards from front to back. In this case not only is the wheel base shortened as compared with the engine shown in Fig. 11; but the weight on the hind axle, owing to its position under the ashpan, is increased as compared with engines having the hind coupled axle behind the firebox. The distribution of weight in such an engine, with inside cylinders 17 ins. diameter by 24 ins. stroke, and wheels 5 ft. 0 ins. diameter, has been

Leading axle	10·64 tons
Middle axle	11·57 „
Hind axle	9·73 „
Total adhesion weight . .	<u>31·94 „</u>

the weight required for adhesion being 24·53 tons, and the wheel base 15 ft. 6 ins.

Fig. 14, Plate 28. The construction of engines having Six Coupled wheels with Outside cylinders, although frequently met with on the continent, is in this country very unusual, since such an arrangement aggravates the disproportion between the weight upon the leading and that upon the hind axle, when the hind axle is placed behind the firebox; although in the cases where the axles are all under the boiler, the greater weight and more forward position of the outside cylinders tends in some measure to counterbalance the overhanging firebox. The distribution obtained in an outside-cylinder engine with overhanging firebox, having cylinders $17\frac{1}{4}$ ins. diameter by $24\frac{1}{2}$ ins. stroke, and wheels 4 ft. 3 ins. diameter, has been

Leading axle	11·20 tons
Middle axle	10·46 „
Hind axle	10·95 „
Total adhesion weight . .	<u>32·61 „</u>

the weight required for adhesion being 30·35 tons, and the wheel base 11 ft. 0 ins.

For Mineral and Coal traffic, engines are frequently constructed having six wheels coupled and with tanks for their water and fuel supply. As in the case of other engines with the hind wheels coupled, so here the position of the tanks can be so arranged as to

equalise the unfavourable distribution of weight upon the hind wheels when the hind axle is placed behind the firebox; since by fixing a long side or wing tank on each side of the engine over the middle and hind axles, it becomes possible to adjust the weight on these two axles in such a manner as to be somewhat in proportion to that upon the leading axle, when the fuel and water supply is at its average amount. The distribution of weight obtained in an engine of this class, with cylinders 16 ins. diameter by 24 ins. stroke, and wheels 4 ft. 6 ins. diameter, has been

Leading axle	9.80 tons
Middle axle	10.85 „
Hind axle	9.80 „
Total adhesion weight . . .	<u>30.45</u> „

the weight required for adhesion being 24.13 tons, and the wheel base 12 ft. 6 ins.

In some instances such engines are constructed with the tank under the footplate, but these are again subject to the disadvantage of too great a variation in the weight upon the hind wheels, depending upon whether the tank and fuel boxes are empty or full. In an engine built thus, with cylinders 16 ins. diameter by 22 ins. stroke, and wheels 3 ft. 10 ins. diameter, the distribution has been

Leading axle	8.40 tons
Middle axle	10.62 „
Hind axle	9.79 „
Total adhesion weight . . .	<u>28.81</u> „

the weight required for adhesion being 25.96 tons, and the wheel base 13 ft. 5 ins.

On Mineral railways having sharp curves it is frequently desired to reduce the wheel base to the smallest possible limit, and consequently all the axles of the engines are placed between the firebox and smokebox. Under these circumstances the tank has to be placed on the top of the boiler, and so arranged that whether full or empty each pair of wheels shall be proportionately loaded and relieved. The distribution of weight in such an engine, with inside cylinders 16 ins. diameter by 24 ins. stroke, and wheels 4 ft. 6 ins. diameter, has been

Leading axle	8.50 tons
Middle axle	11.00 „
Hind axle	10.75 „
Total adhesion weight . . .	<u>30.25 „</u>

the weight required for adhesion being 24.13 tons, and the wheel base 11 ft. 8 ins.

Fig. 15, Plate 28. Bogie Engines have been rendered necessary by the construction of railways with not very heavy permanent way and sharp curves; in consequence of which a short wheel base has become a necessity, and in heavy engines it has been found requisite to carry the weight of the leading end upon four wheels instead of upon two, the wheels being placed very far forward and thereby necessitating considerable lateral freedom of motion upon the curves. Engines of this class working with tenders and having their middle and hind wheels coupled are used almost universally on the American railways, both for passenger and goods traffic. It appears that in engines so constructed a considerable amount of the weight of the engine which ought to be available for adhesion is carried on the bogie wheels, in consequence of the increased weight of the engine involved in the use and construction of the bogie, together with the heavy spark-catching chimney, and the usual cow-catcher in front, as shown in Fig. 15. An incidental objection to the use of bogies is the necessity for employing wheels of small diameter, so as to obtain clearance under the frames and cylinders, their diameter being usually less than that of the carriage and wagon wheels. The weights obtained in an engine of this kind, with outside cylinders 13 ins. diameter by 18 ins. stroke, and four coupled driving wheels 5 ft. 6 ins. diameter, have been

Bogie axles	8.00 tons
Middle axle	8.50 tons
Hind axle	7.50 „
Total adhesion weight . . .	<u>16.00 „</u>

the weight required for adhesion being 9.79 tons, and the wheel base 13 ft. 6 ins. from centre of bogie to hind wheel centre. When it is desired to carry a water tank in such engines, the tank may be so arranged as to throw all the additional weight upon the coupled

wheels, and indeed as far as possible to equalise the weight upon them.

With regard to the general principles of distribution of weight upon the axles of six-wheeled locomotive engines, it seems to be the common opinion that the middle axle, to which the power is first applied from the cylinders, should carry the greatest weight, and next to this the leading axle, thus leaving the lightest load to be borne by the hind axle; this arrangement being thought desirable with a view to keep the front of the engine heavier on the rails than the hind end, and so secure it from risk of jumping off. The writer would however suggest whether such a necessity for placing a greater load on the leading than on the hind axle really exists; since it seems unlikely that any engine with a reasonable weight upon the leading axle, and consequently with a reasonably strong spring for keeping the wheels down on the road in the event of blows being received, could ever leave the line merely because the hind axle carried a greater amount of weight than the leading axle. It should further be remembered that in all cases where the hind wheels of an engine are coupled and the leading wheels not so, an arrangement which is becoming more and more frequent, it is absolutely desirable, in order to obtain the maximum adhesion, that the hind coupled wheels should carry a weight nearly equal to that upon the middle wheels, and consequently greater than that usually placed upon the leading wheels. In this respect there is a disadvantage in the employment of engines with outside cylinders, because of the greater weight of the front part of the engine in that arrangement, and the consequent loss of a larger proportion of the total weight for adhesion. This objection applies only to outside cylinder engines having their leading wheels uncoupled: but on the other hand to couple the leading wheels of such engines involves considerable complications and difficulties.

Another point of interest connected with the distribution of the weight is the effect produced upon the stability of a locomotive by the difference between the portion of weight carried upon each *spring* and the total weight carried by the *rail* at each wheel: in all

the preceding examples of distribution that have been given, the weights stated are those upon the rails at each axle. In engines with inside cylinders this difference is often very considerable, and must exercise a great influence upon the tendency to rise and fall on the springs; and often when, in taking account of the weight upon the rails only, the front pair of *wheels* is found to press upon the rails with a less weight than the hind wheels, the fact is lost sight of that the weight upon the leading *springs* is greater than upon the hind pair, and the tendency to leave the road is consequently diminished in front. This arises from the circumstance that, in the case of the middle and hind coupled wheels, the weight of the parts not carried by the springs—namely the wheels, axles, axleboxes, springs, and gearing—is greatly in excess as compared with the weight of the corresponding parts not carried by the front springs. As an instance may be taken one of the engines already referred to, Fig. 8, Plate 26, being an inside-cylinder engine with cranked middle axle, having cylinders 17 ins. diameter by 22 ins. stroke, leading wheels 4 ft. 0 ins. diameter, middle and hind wheels coupled 6 ft. 6 ins. diameter. Here the weights upon the rails and upon the springs at the several axles were as follows:—

	Weight upon Rails.	Weight upon Springs.
Leading axle	9·36 tons	7·91 tons.
Middle axle	11·57 „	7·77 „
Hind axle	9·71 „	6·78 „

thus showing that the mass of the engine above the springs, and having liberty to leave a line parallel to the plane of the railway, had a sufficient excess of weight in front to “keep down the nose,” amounting to 1·13 tons excess of weight upon the leading springs as compared with the hind springs; although the weight obtained for adhesion by coupling the hind wheels was 0·35 ton greater than if the front wheels had been coupled instead. In this example the proportion of the weight carried on the springs to the total weight upon the rails at each axle was, at the leading axle 85 per cent., at the middle axle 67 per cent., and at the hind axle 70 per cent.; the total weight carried upon the springs being 73 per cent. of the total weight on the rails.

The difficulties now presented to the proper distribution of weight upon the axles of locomotives are considerably increased by the prevalent adoption of sharper curves in the construction of railways than were formerly used, and the consequent necessity for shortening the wheel base. Continental engineers have been driven by similar difficulties to adopt in a large number of cases the plan of placing all the axles of the engine under the cylindrical part of the boiler, thus gaining a short wheel base by letting the firebox overhang behind. This plan is liable to considerable objection, on account of overloading the hind axle of the engine to such an extent as to cause a galloping motion when running fast; and as it has now become more necessary, from the introduction of coal as fuel and for other reasons, to adopt fireboxes of larger dimensions and increased weight, the objection to their overhanging the hind axle has been proportionately increased. At the same time the arrangement of sloping firegrate already referred to greatly facilitates the adjustment of weight upon the hind wheels; since, when the frames are placed outside the wheels, the axle may pass across under the firebox at any point necessary to bring the desired weight upon it, so that not only is the long wheel base avoided, but also the overhanging of the firebox; while the instability of the engine consequent upon the latter is guarded against. An unavoidable weight is often thrown upon the leading uncoupled axles of locomotives by the obligation of keeping the middle axle sufficiently far back to get adequate length of connecting rod: hence it becomes necessary in some instances either to increase the length of the boiler in order to obtain sufficient weight behind the middle axle, thus involving a considerable lengthening of the wheel base; or else to adopt the heavy sloping firebox accompanied by outside frames.

By care in arranging the position of the middle axle of a locomotive in relation to the centre of gravity of the mass carried upon the springs (not the centre of gravity of the whole engine) a fair distribution of the weight may usually be secured. It is evident that only the portion of the engine above the springs can be affected by the adjustment of the spring attachments; and it

will be found that the centre of gravity of this portion varies to the extent of some inches from that of the whole mass of the engine. Taking then as a basis the centre of gravity of this adjustable portion of the engine, the effect produced upon the distribution of the load by any alteration either in the position of the axles or in the screwing up of the spring links can be readily calculated by dividing the total adjustable load in such proportions that the products of the several loads upon the axles multiplied by their respective distances from the centre of gravity shall balance one another on each side of that centre.

In the following example the results thus obtained by calculation were verified by the actual weights upon a weighing machine, in the case of a single passenger engine, having the centre of gravity of the adjustable load $8\frac{1}{2}$ inches in front of the middle axle, as shown at G in Fig. 16, Plate 29, the leading axle being 6 ft. 8 ins. in front of the middle axle, and the hind axle 8 ft. 0 ins. behind it. The several distances of the axles from the centre of gravity were consequently, leading axle $71\frac{1}{2}$ ins. forward, and middle and hind axles $8\frac{1}{2}$ and $104\frac{1}{2}$ ins. respectively backward, as shown in Fig. 16. The middle driving springs were screwed up in the three weighings according to the several different adjustments enumerated, the load then apportioning itself correspondingly at the leading and hind axles, as follows:—

	Leading axle. Tons.		Middle axle. Tons.		Hind axle. Tons.		Total Weight. Tons.
1st weighing	11·85	+	10·20	+	8·05	=	30·10
2nd ,,	10·55	+	12·50	+	7·05	=	30·10
3rd ,,	9·65	+	14·20	+	6·25	=	30·10

These being the actual results ascertained by the weighing machine, the following are the results obtained by calculation of the distribution of the weight, starting in each case with the respective loads above given at the middle axle. The constant weight at the several axles (that is the weight of the wheels, axle, axleboxes, springs, and gearing) was, leading 1·76 tons, middle 3·66 tons, and hind 1·68 tons; total 7·10 tons, leaving 23·00 tons adjustable weight above the springs.

Calculated Distribution of Weight.

		Leading axle.	Middle axle.	Hind axle.	Total Weight.
		Tons.	Tons.	Tons.	Tons.
1st weighing. 10·20 tons at Middle axle. (See Note A.)	Adjustable weight	10·09	6·54	6·37	23·00
	Constant „	1·76	3·66	1·68	7·10
	Total . . .	11·85	10·20	8·05	30·10
2nd weighing. 12·50 tons at Middle axle. (See Note B.)	Adjustable weight	8·83	8·84	5·33	23·00
	Constant „	1·76	3·66	1·68	7·10
	Total . . .	10·59	12·50	7·01	30·10
3rd weighing. 14·20 tons at Middle axle. (See Note C.)	Adjustable weight	7·91	10·54	4·55	23·00
	Constant „	1·76	3·66	1·68	7·10
	Total . . .	9·67	14·20	6·23	30·10

The effect that would be caused in relieving the leading axle of a portion of the weight by shifting the position of the middle axle in this engine is ascertained by the following calculation for a case of shifting the axle 6 ins. more forward, as shown by the dotted position in Fig. 16, Plate 29, in the instance of the second of the above adjustments of the middle springs, with 12·50 tons total at the middle axle :—

(See Note D.)	Leading axle.	Middle axle.	Hind axle.	Total Weight.
	Tons.	Tons.	Tons.	Tons.
Adjustable weight . .	8·53 . .	8·84 . .	5·63 . .	23·00
Constant „ . .	1·76 . .	3·66 . .	1·68 . .	7·10
Total	<u>10·29</u> . .	<u>12·50</u> . .	<u>7·31</u> . .	<u>30·10</u>
In place of the Actual weights }	<u>10·55</u> . .	<u>12·50</u> . .	<u>7·05</u> . .	<u>30·10</u>

the effect produced being therefore a transference of $\frac{1}{4}$ ton from the leading to the hind axle by shifting the middle axle 6 ins. forwarder.

	Tons.	Ins.	Tons.	Ins.	Tons.	Ins.
Note A.	10·09	$\times 71\frac{1}{2}$	= (6·54 $\times 8\frac{1}{2}$)	+	(6·37 $\times 104\frac{1}{2}$)
„ B.	8·83	$\times 71\frac{1}{2}$	= (8·84 $\times 8\frac{1}{2}$)	+	(5·33 $\times 104\frac{1}{2}$)
„ C.	7·91	$\times 71\frac{1}{2}$	= (10·54 $\times 8\frac{1}{2}$)	+	(4·55 $\times 104\frac{1}{2}$)
„ D.	8·53	$\times 71\frac{1}{2}$	= (8·84 $\times 2\frac{1}{2}$)	+	(5·63 $\times 104\frac{1}{2}$)

The respective leverages are marked in Fig. 16, Plate 29.

In the case of engines with the middle and hind wheels coupled, Compensating or Connecting Levers are frequently employed, as shown in Fig. 17, Plate 29, for the purpose of equalising the weights on the two driving axles. The back end of the middle spring and the front end of the hind spring are connected together by the lever, which is attached to the frame of the engine by a centre pin A on which it vibrates, the other two ends of the springs being each connected direct to the frame as usual. When the two arms of the lever are equal in length, the weights carried by the two springs are necessarily rendered equal, however different they may have been when the springs were attached direct to the frame at both ends, before connection by the lever; because the forces of tension at the two ends of an equal-armed lever must always be equal. This change in the distribution of the load is produced by the more heavily loaded middle spring becoming partially released from compression, adding at the same time to the compression of the more lightly loaded hind spring through the action of the connecting lever, as shown in Fig. 18. The effect of the connecting lever is thus to blend the two springs into one, and to produce the same distribution of load as if the middle and hind axles were removed and replaced by a single axle fixed in the position of the axis A of the connecting lever and carrying their combined load; thereby transforming the engine in effect into a four-wheeled engine. Exactly the same result however can be produced without the connecting lever, by simply screwing up the hind spring to the same extent as it is compressed by the action of the lever, and slacking back the middle spring to the corresponding extent. But the objectionable result then arises in both cases alike, that a portion of the load of which the middle wheels are relieved is thrown upon the leading wheels, thereby causing the loss of so much of the total driving adhesion; since the leading axle is the fulcrum upon which the engine is lifted when screwing up the hind springs, as shown by the diagram, Fig. 19, Plate 29. Where the connecting lever is inserted between the leading and middle springs, the same remark applies to the effect produced on the distribution of the weight as where the middle and hind springs are connected by

a lever: that no distribution of the weight is thereby obtained which cannot be 'equally obtained with independent springs. It has to be remarked however that, in consequence of the engine being transformed virtually into a four-wheeled engine by the insertion of connecting levers, the original distribution of the weight can never be altered in any degree after the engine is built and fitted with the levers; whereas with independent springs the six-wheeled engine retains the full advantage of its 'three axles, whereby the original distribution of the weight can be altered at any subsequent time within a very extensive range, as is seen by the example already given of the three weighings of the same engine. Moreover with a connecting lever of equal arms, although the weights upon the connected springs are rendered equal, the pressure of the wheels upon the rails and consequently their adhesion will still be unequal, on account of the greater weight of the middle axle and gearing.

These conclusions are illustrated by the following examples, obtained by actual trials of the distribution by means of the accompanying working model, constructed for the purpose of demonstrating the real action of the connecting lever. The model represents an engine frame supported by spring balances at three points corresponding to the position of the three axles in the engine, and weighted by adjustable weights at the point where the centre of gravity of the portion of the engine above the springs would be situated, with a connecting lever of equal arms between the middle and hind, or the leading and middle springs, capable of being thrown in or out of action as desired; the scales of the spring balances thus affording a ready means of reading off accurately the actual distribution of the weight at each spring in the several trials. The model was weighted to represent an engine having an adjustable weight of 22·37 tons, with the centre of gravity in front of the middle axle; and the connecting lever was inserted first between the middle and hind springs, and afterwards between the leading and middle springs. The weight was first distributed on the several springs by means of the spring links alone, the connecting lever being fixed so as to be out of action; the

lever was then released and thrown into action, when the weight assumed the new distribution recorded; after which this last distribution was again effected by means of the independent springs, the connecting lever being thrown out of action as before. The slight discrepancies in the results arose from the friction of the model, which could not be entirely got rid of.

With the connecting lever between the middle and hind springs, the following were the results read off from the spring balances:—

	Leading spring. Tons.	Middle spring. Tons.	Hind spring. Tons.
Original distribution without connecting lever	9·37	9·00	4·00
Lever in action	11·12	5·72 connected,	5·52
Same distribution with independent springs	11·11	5·73	5·51

With the connecting lever between the leading and middle springs, the results obtained were the following:—

	Leading spring. Tons.	Middle spring. Tons.	Hind spring. Tons.
Original distribution without connecting lever	10·00	7·50	4·87
Lever in action	9·13 connected	9·10	4·13
Same distribution with independent springs	9·12	9·10	4·17

The above results show therefore that nothing is gained by the application of the connecting lever in equalising the loads on the connected springs that cannot be also obtained without the lever by independent springs. This is a point of some importance to be clearly realised, because an opinion has prevailed that the use of the connecting lever gives facilities not otherwise to be obtained for adjusting the distribution of the weight.

The first of the above examples, with the connecting lever between the middle and hind springs, shows also the effect of the equal-armed lever in that case in throwing an increased weight upon the leading spring: for while the middle spring is relieved to the extent of 3·27 tons load, only 1·52 tons of this is added to the compression of the hind spring, and the difference, 1·75 tons, is all thrown upon the leading spring. This case is illustrated by the

diagrams in Plate 29, where Fig. 17 shows the position of the springs in the original distribution without the connecting lever A being in action ; and Fig. 18 represents the result of the lever coming into action, the hind spring being thereby further compressed, the middle spring relieved, and an additional load thrown upon the leading spring.

The use of the connecting lever has however an independent advantage in passing over an inequality in the rails, because the second spring connected by it partly shares in each deflection of the first spring, and the play of the first spring is thereby diminished to that extent ; but the same result is attained with independent springs, by employing proportionately longer springs wherever practicable. It has to be noticed moreover that with the connecting lever the objection is incurred of causing the breaking down of both springs in the event of the failure of either of them. In connecting the leading with the middle springs, levers with unequal arms have sometimes been employed, the length of the arms being inversely proportionate to the loads on the two springs, so that the distribution of the load is not disturbed by inserting the levers. In this case the levers have the same action as before of lessening the play of the springs in running over any inequality in the rails ; but the same objection of causing a break down of both springs by any failure of either applies as before, though with greater force in the case of the leading springs on which the safe running of the engine depends.

Mr. ROBINSON exhibited the working model constructed for the purpose of illustrating the action of the connecting lever, and showing that any distribution of the weight obtained with the connecting lever was effected equally well with independent springs by a corresponding adjustment of the spring links. The particular case of a six-wheeled engine with the four hind wheels coupled, having the centre of gravity in front of the middle axle, was illustrated by means of the model, and it was shown that the insertion of a connecting lever to equalise the weights on the middle and hind wheels caused an actual loss of driving adhesion, by throwing an increased load on the leading wheels.

The CHAIRMAN observed that it appeared the only point gained by the use of a connecting lever was that it ensured that the distribution of the load between the connected wheels in running should always remain in the proportion originally determined upon by the length of the arms of the lever: but nothing was gained as regarded the actual distribution of the load on the several wheels, which could not be accomplished as well by a proper adjustment of independent springs. He enquired to what extent the friction of the connecting lever was found to affect the correct distribution of the load upon the springs between which it was placed.

Mr. ROBINSON replied that where the connecting lever was constructed to turn upon a round centre pin fitting into a hole in the lever, the friction was so great from the very heavy pressure upon the small surface of the pin that the results obtained in the model could not be realised by actually weighing the engines, and consequently the intended distribution of the weight by the lever was not really maintained in practice. In some of the Great Western engines fitted with connecting levers this friction had been reduced by using knife-edge bearings for the levers, instead of the round centre pins; but still the friction of the axleboxes between the guards was found to interfere very much with the intended results being obtained.

Mr. C. W. SIEMENS remarked that the friction would no doubt have the effect of preventing the due action of the connecting lever while the engine was at rest; but he thought that in running

the shaking produced would impart to the lever a concussive motion favouring its speedy adjustment to the varying conditions of load which it was intended to equalise.

Mr. F. W. WEBB observed that the results obtained by the model were corroborated in practice, as regarded the increase of weight thrown upon the leading wheels where a connecting lever was placed between the middle and trailing wheels: he had known several cases of such engines where the connecting levers had been taken off, and it had been found that $1\frac{1}{2}$ tons had been removed from the leading wheels by the change, and added upon the driving wheels. He might mention that some four-wheeled inside-cylinder tank engines had been constructed by Mr. Ramsbottom for shunting at various stations on the London and North Western Railway, having the firebox entirely inside the cylindrical barrel of the boiler, so that the hind axle could be carried back far enough to give an exactly equal distribution of weight on the front and hind wheels. The firebox was cylindrical and made of Bessemer steel, and the tubes were also steel; and the steam was as dry as from an ordinary boiler with low firebox. These engines had been at work some time, but for shunting purposes only, not being able to make steam fast enough for running.

Mr. COLBURN said that connecting levers were used in all American locomotives, not so much in reference to the distribution of the weight as to promote the ease and steadiness of the engines in running over rough lines: and there was no doubt that whether on rough or smooth lines the engines worked better with them. The American engines always had a bogie in front, according to the diagram exhibited, and engines of that construction had been brought over for working the Birmingham and Gloucester line many years ago. In some early American engines the driving wheels were placed behind the firebox; and afterwards, as the engines grew heavier, a second pair of driving wheels was added in front of the firebox, with an independent spring for each wheel. Several engines were built on this construction, but they did not seem to answer; and some of these were altered by Mr. Harrison, the inventor of the cast iron boiler that had been described, by

putting in a connecting lever, which was placed above the wheels, the ends bearing upon the axleboxes, with an inverted spring between the wheels, attached by links to the lever: he built a large number of locomotives on that plan in St. Petersburg for the St. Petersburg and Moscow Railway.

There was a large amount of weight below the springs in American locomotives, as they were made with cast iron driving wheels, which were very heavy, and the tyres were found to stretch in consequence unless they were put on very thick. In an engine of 28 tons weight there was about 6 tons below the springs, in the four driving wheels with their axles and axleboxes; and with the addition of the bogie there was thus about one third of the whole weight of the engine that was not relieved by springs at all. The wheels were now made with wood blocks under the tyres, cut cross grain of the wood, as a bed for the tyres upon the wheels, in order to reduce the injurious effect of their great weight and rigidity in passing over any inequalities in the road. The wheel base of the bogie was generally about the same as the gauge of the line, from 5 ft. 3 ins. to 5 ft. 6 ins.; and the wheels themselves were usually 2 ft. 9 ins. diameter, the same as those on the bogies of the carriages; sometimes they were as small as 2 ft. 2 ins. diameter. The usual distribution of the weight was about 3-5ths on the driving wheels, and 2-5ths on the bogie, or sometimes 2-3rds on the driving wheels, and 1-3rd on the bogie: the position of the pivot of the bogie, being so far forward, allowed of keeping the driving wheels further back, whereby a shorter coupling rod and longer connecting rod could be used.

The practical effect of the connecting levers in running was to ease the motion of the engine, which was much needed on the bad roads of the American railways. He had himself experienced their beneficial action in travelling on the engine from Augusta to Atlanta, 171 miles, over a very rough road, and all the time of running the connecting levers were in a complete dance with continued oscillations, but the engine ran very smoothly and steadily. The engines had to be hung with greater provision for elasticity for running over those rough roads, and skeleton springs

with open plates were generally used, the spring hangers being also supported on india-rubber washers. In some instances the connecting lever itself was a spring, which made the footplate of the engine very easy in running.

Mr. W. M. NEILSON considered the connecting levers were without doubt a valuable adjunct to an engine for running on bad roads; but as far as the distribution of the weight was concerned they certainly had no advantage over independent springs, and in the case that had been pointed out in the paper they had the disadvantage of throwing an increased load upon the leading wheels while diminishing at the same time the driving adhesion. He could fully confirm what had been stated as to the effects of the connecting lever in the American engines, having travelled over many of the American railways on the ordinary four-wheel-coupled bogie-engines fitted with the levers, and at a good speed of running there was not any objectionable unsteadiness in the engine, notwithstanding the rough state of the roads: but he should not have thought it safe to run at the same speed with an ordinary English locomotive over the same description of road. Even on the English lines he thought the connecting levers would give an advantage in smoothness of running, as the road could not be maintained always in the very best condition, and was by no means perfect at its best. The action of the levers was beneficial both to the permanent way and to the engine itself, by reducing the effect of shocks arising from inequalities of the road; and in the same manner they conduced to the safety of the engine in running, rendering it less easy for the wheels to leave the rails. With independent springs the effect of running over an obstacle or elevation in the rails was to lift the engine in proportion to the rigidity of the springs; but if the same springs were connected by a lever, each would be deflected only half the amount, and the engine would be lifted only half as much as before.

Mr. ROBINSON observed that the effect of the connecting lever when the engine ran over an obstacle was to cause the two connected springs to be both deflected simultaneously, so that the engine would be lifted a smaller amount by the shock than if one

spring only had been acting at a time. The lever had thus the effect of virtually doubling the length of each spring; and although the same result of a small lift might be obtained without the lever if springs of double the length were used, yet the length of spring was practically limited in an engine by the confined space, so that the springs were often not more than 2 ft. 6 ins. long, and in such cases the connecting lever had the advantage of practically lengthening the short springs.

Mr. E. REYNOLDS did not think that any lengthening of the springs would give the same ease of motion that was obtained by a connecting lever. In the Bloomer engines of the London and North Western Railway having connecting levers between the leading and middle springs, the leading wheels were heavily loaded with about $11\frac{1}{2}$ tons upon them; and the extreme amount of inequality likely to be met with in the rails on English lines might be taken at $\frac{1}{2}$ inch, which corresponded to an additional load or compression of 4 or 5 tons upon the springs, as they were very short and rigid. Hence a rise of $\frac{1}{2}$ inch in the rails would cause 4 or 5 tons greater pressure upon the rails for the moment at that point; but by the connecting levers the leading and middle springs would share the additional weight between them under all circumstances, and so relieve both the rails and the engine from a great part of the shock that would otherwise be felt, the engine being lifted only by the amount of rise at the centre of the lever.

Mr. COLBURN remarked that connecting levers were used upon all the bogies in America both for engines and carriages; and the bogie itself having also the effect of reducing any disturbance by one half, the result of an inequality of $\frac{1}{2}$ inch in the rails would be to lift the centre of gravity of the engine or carriage only 1-8th inch. In the long carriages the distance from centre to centre of the bogies was 32 feet, and the carriages were also much lower than on English railways; the result was that they ran with greater steadiness, though the speed was certainly not so great as in the fast trains in this country.

The CHAIRMAN remarked that upon the American railways, which were comparatively speaking imperfectly constructed and

laid down more with the object of covering a great extent of country than with a view to permanent durability of the works, the necessity for the use of connecting levers must have been much more strongly felt than in England; and hence the general adoption of the bogie, which was itself a connecting lever, both for engines and carriages. He had many engines running with connecting levers on the London and North Western Railway, but had not found that they ran more steadily on that line apparently than engines without the levers; though there could be no question that the introduction of the levers would reduce the disturbance of the engine to a certain extent where the road was not in first-rate condition. Any such arrangement was however in his opinion as much worse for the road as it was better for the engine.

He proposed a vote of thanks to Mr. Robinson for his paper, which was passed.

The Meeting then terminated.

PROCEEDINGS.

2 AND 3 AUGUST, 1864.

The ANNUAL PROVINCIAL MEETING of the Members was held in the Institution Rooms, St. George's Place, Glasgow, on Tuesday, 2nd August, 1864; ROBERT NAPIER, Esq., President, in the Chair.

The Minutes of the last General Meeting were read and confirmed.

The PRESIDENT announced that the Ballot Lists had been opened by the Committee appointed for the purpose, and the following New Members were duly elected :—

MEMBERS.

JAMES GEORGE BECKTON,	. . .	Whitby.
JAMES CAMPBELL,	. . .	Matlock.
THOMAS EDWARD DUNN,	. . .	Allahabad, India.
ANTONIN ETIENNE,	. . .	Seville, Spain.
WILLIAM EDWARD EVERITT,	. . .	Birmingham.
THOMAS FLEET,	. . .	Westbromwich.
JOHN FRANKISH,	. . .	Manchester.
WILLIAM ISAAC HETHERINGTON,	. . .	Manchester.
SAMPSON ZACHARY LLOYD,	. . .	Wednesbury.
WILLIAM MARTLEY,	. . .	London.
ROBERT RAMAGE,	. . .	Dublin.
DUNCAN SHAW,	. . .	Cordova, Spain.
THOMAS SPITTLE,	. . .	Newport, Mon.
JAMES SWINDELL EVERS SWINDELL,	. . .	Brierley Hill.
THOMAS THOMAS,	. . .	Pontypool.

HONORARY MEMBERS.

CHARLES T. PARSONS,	.	.	Birmingham.
ABEL PEYTON,	.	.	Birmingham.

The following paper, by Mr. James M. Gale of Glasgow, Resident Engineer of the Water Works, communicated through Mr. Walter M. Neilson of Glasgow, was then read:—

ON THE MECHANICAL APPLIANCES
OF THE LOCH KATRINE WATER WORKS
FOR THE SUPPLY OF GLASGOW.

BY MR. JAMES M. GALE, OF GLASGOW.

Previous to 1860 that part of Glasgow lying on the north bank of the river Clyde, or about three fourths of the whole city, was supplied with water drawn from the river at two pumping stations $2\frac{1}{2}$ and $3\frac{1}{2}$ miles above Glasgow Bridge respectively. The remaining part of the city, that on the south side of the river, was supplied, and in greater part is still supplied, by the Gorbals gravitation works, established in 1847 on a small stream about 7 miles south of the city. The impure quality of the water drawn from the river had induced the corporation of Glasgow to purchase the whole of the works from the two existing water companies, and to promote a scheme for supplying the city from Loch Katrine, the well known Loch in the Perthshire Highlands. The works were commenced in 1856, were opened by Her Majesty on the 14th October 1859, and were completed and the water introduced to the greater part of Glasgow early in 1860. The whole works were executed from the designs and under the superintendence of Mr. J. F. Bateman.

Fig. 1, Plate 30, is a general plan showing the drainage area of Loch Katrine and the adjacent Loch Vennachar, together with the two smaller Lochs, Achray and Drunkie, and the inlet at A from Loch Katrine to the line of aqueduct.

Fig. 2, Plate 31, is a general plan showing the entire line of aqueduct for conveying the water from Loch Katrine to Glasgow.

Fig. 3, Plate 32, is a longitudinal section along the entire course of the works from Loch Katrine to Glasgow, showing the situation of the principal tunnels, aqueduct bridges, and syphon pipes throughout the course of the aqueduct.

The drainage area to the Loch Katrine Water Works amounts to 45,800 acres, or about 72 square miles, as shown in the plan, Fig. 1, Plate 30; and includes Loch Katrine, Loch Achray, Loch Vennachar, and Loch Drunkie. Loch Achray has not been appropriated for the use of the water works, but works have been constructed at the outlets of the three other lochs whereby a large amount of storage has been obtained at comparatively little cost. A masonry dam with four sluices and a waste weir 100 feet long have been erected at the outlet of Loch Katrine at the point marked B in the plan, Fig. 1. The level of the water is thus raised 4 feet above its former summer level, and the sluices also admit of the water being drawn down 3 feet below the former summer level; thus giving a control over the contents of the loch to the extent of 7 feet in depth, and a storage capacity amounting to 910 million cubic feet. The portions shown black around the margin of the loch in Fig. 1 indicate the additional area of water obtained by the raising of the loch, as also in the case of Loch Vennachar and Loch Drunkie. The drainage area to Loch Katrine alone is 22,800 acres, and the area of the loch itself at its summer level 3000 acres, or about one seventh of the whole drainage area. The district is very rugged and mountainous, as seen from the plan, Fig. 1, and the longitudinal section, Fig. 3; and in some places, especially near the pass of the Trosachs, very picturesque. The level of the water in Loch Katrine is 362 feet above the level of the sea; and the lip of the basin which surrounds it, except near the point A, Fig. 1, where the water is drawn off into the aqueduct, has a minimum elevation of 1000 feet above the sea, and at one place, Ben Venne, rises to 2388 feet. The rocks of the district are mica schist, one of the primary deposits, and are precipitous, very hard, nearly insoluble, and yielding water of great purity. The water drawn from the loch contains only about $2\frac{1}{4}$ grains of soluble matter per gallon and has a hardness of 0.8° on Dr. Clark's scale; in which a hardness of 1° is that due to one grain of chalk dissolved in one gallon of distilled water, the hardness being the property of destroying soap. The district contains very little land that can be cultivated, and the covering of soil or peat on the top of the rock is not deep enough to affect the

colour of the water in the loch, even during high floods. Also there need be no apprehension of the quality of the water ever becoming injured by agricultural operations, or by drainage from populous districts: at present there are only ten houses on the 36 square miles of country which drains into the loch. The fall of rain in the district is very great: in the valley of the Duchray on the eastern side of Ben Lomond, Fig. 1, and in Glen Gyle at the head of Loch Katrine, there is in some years a fall of 100 inches; while in the more open country lower down the valley the fall is about six tenths of that higher up. The table appended shows the amount of rainfall at several points, since rain gauges were established in the district.

The works at the lochs have been arranged on a scale sufficient to ensure a supply to Glasgow during the driest season of 50 million gallons a day, and to provide compensation water to the river Teith in addition. The supply for the city is drawn exclusively from Loch Katrine, and the compensation water principally from Loch Vennachar and Loch Drunkie. The compensation water was fixed by agreement with the proprietors and others having an interest in the rivers Teith and Forth at 40,500,000 gallons per day, or an average of 4500 cubic feet per minute, to be given out from Loch Vennachar at the rate of 6000 cubic feet per minute from 1 o'clock a.m. to 1 o'clock p.m., and 3000 cubic feet per minute from 1 p.m. to 1 a.m. of each day in the year.

This additional quantity of water has been obtained by constructing a masonry dam at the outlet of Loch Vennachar, at the point C in the plan, Fig. 1, Plate 30, with a waste weir 150 feet long. This is shown in Figs. 4 to 6, Plates 33 and 34. The dam is 110 feet long, Fig. 4, Plate 33, and is furnished with eleven cast iron sluices to regulate the flow of the water, the top of the dam being carried up and roofed in to form a protection for the working gearing of the sluices. The loch has been raised by the dam 5 feet 9 inches above its former summer level, and it can be drawn down by the sluices 6 feet below the summer level. A new channel was cut for the river, as shown at C in the plan, Fig. 1,

700 yards long and 50 feet wide, in order to allow of the water in the loch being drawn down to this further depth. The compensation gauge weir, placed at the lower end of the new river channel, consists of a continuous cast iron plate 100 feet long, brought to a thin edge at top, over which the water flows with a depth of $3\frac{1}{4}$ to $5\frac{1}{4}$ inches when the statutory quantity only is being discharged. The area of Loch Vennachar at its former summer level was 865 acres, and at the level to which it has been raised it is about 1000 acres, as shown by the black portions round the margin of the loch in the plan, Fig. 1. The storage capacity included in the range of level of 11 feet 9 inches depth afforded by the works is 425 million cubic feet.

The works at Loch Drunkie, Fig. 1, Plate 30, consist of two earthen embankments with puddle in the centre of each, protected by stone facing on the inner slopes in the usual manner. The northern embankment is 150 yards long, and the other, which is at the original outlet of the loch, is 40 yards long. The level of the loch has been raised 25 feet, and the area increased from 78 to 137 acres, as shown by the black portions surrounding the loch in Fig. 1, thus affording storage to the extent of 120 million cubic feet. The water is discharged from the loch by a cast iron pipe, 24 inches diameter, laid through the deepest embankment.

The total amount of storage provided by the works at the three lochs is therefore 1455 million cubic feet, equal to a supply for 100 days of 50 million gallons per day for the city and $40\frac{1}{2}$ million gallons per day for compensation water to the river Teith, without taking into account the natural flow of the streams running into the lochs. At the present rate of consumption of water in the city, this storage is equal to 152 days' supply, including the compensation water.

As the Teith is a good salmon river, it was necessary to provide for the passage of the fish at the masonry dams at the outlets of Loch Vennachar and Loch Katrine. This has been done at Loch Vennachar by forming four salmon stairs at different levels to suit the varying level of the loch, of a width of 6 feet between the side walls. These are shown at D D in Fig. 4, Plate 33; and a

longitudinal section of the highest one is shown in Fig. 5, Plate 34. The stairs have a general inclination of 1 in 12, and terminate at the upper end next the loch with cast iron sluices, which open by being moved downwards, thus allowing the water to fall over as over a weir. The detail of one of these salmon sluices is shown in Figs. 7 to 9, Plate 35. The sloping channels are formed into a succession of deep pools by planks upon edge placed across the channel, as shown at E E in Fig. 5, Plate 34, over which the water falls a depth of from 15 to 20 inches to the lower level. At Loch Katrine there are only two of these salmon stairs, but otherwise the arrangements are similar.

The point of inlet A, Fig. 1, Plate 30, where the water is drawn from Loch Katrine into the aqueduct for the supply of the city, is about 5 miles from the bottom of the loch and $2\frac{1}{2}$ miles from the top. The water is first admitted from the loch into a basin 55 feet long by 40 feet wide inside, through three cast iron sluices, each 4 feet square. Across the middle of the basin is fixed a line of strainers, to keep fish &c. from passing from the loch into the aqueduct. The outlet sluices at B and C, Fig. 1, for discharging the water from the outlets of Loch Katrine and Loch Vennachar, as well as the inlet sluices from Loch Katrine to the aqueduct, are of similar construction. One of the inlet sluices is shown in Figs. 10 to 12, Plates 36 and 37. The cast iron sluice plate F is faced with brass, and works against brass faces on the cast iron frame G, which is securely let into the masonry and is furnished with guides to keep the sluice F in its place. The sluice is raised and lowered by means of the iron screw H working in a brass nut, the screw being turned by a crank and bevil wheels at top.

The length of the aqueduct from Loch Katrine to the service reservoir at Mugdock near Milngavie, as shown on the general plan, Fig. 2, Plate 31, is $25\frac{3}{4}$ miles, and from this reservoir to Glasgow is about 8 miles more; making a total length from Loch Katrine to Glasgow of about 34 miles. The built and tunnelled part of the aqueduct is 22 miles long; it is 8 feet high by 8 feet broad, as shown in the sections, Figs. 13 to 15, Plate 37, and has a uniform

inclination towards Glasgow of 10 inches per mile or 1 in 6336, as shown in the longitudinal section, Fig. 3. Plate 32; and it is all capable of passing 50 million gallons per day. The valleys of the Duchray, the Endrick, and the Blane, Fig. 3, which are crossed by the line of aqueduct and prevent a uniform inclination being obtained throughout, make up an aggregate length of $3\frac{3}{4}$ miles, and are passed by cast iron syphon pipes 48 inches diameter with a mean fall of 1 in 1000 between their extremities. These pipes deliver a little over 20 million gallons per day; and at all the bridges and other places where masonry was required, provision has been made for laying two additional lines of pipes when the increased consumption of water in the city may require this to be done.

The first work on the line of aqueduct upon leaving Loch Katrine is a tunnel through the ridge which separates the valley of Loch Katrine from that of Loch Ard, Fig. 3, Plate 32. The point where the valleys approach nearest to each other was chosen, but even there the length of tunnel required is upwards of $1\frac{1}{4}$ mile, and it is at a depth of more than 500 feet below the top of the hill. Twelve shafts were sunk on the line of tunnel to facilitate the work, five of them being about 450 feet deep. The rock passed through in this tunnel, and in the greater part of the first 10 miles of the aqueduct, which is principally a series of tunnels, is mica slate of the hardest description. Along the margin of Loch Chon the work at some of the faces did not progress at a greater rate than 3 lineal yards in a month, although it was carried on night and day. The cost of the gunpowder alone used in the contract, which extended $7\frac{1}{2}$ miles from the loch, was £10,540; and the average cost of the aqueduct for the same length was more than £13 per yard or £23,000 per mile. Figs. 13, 14, and 15, Plate 37, show sections of the aqueduct at different parts.

The three main valleys on the line of aqueduct are passed by cast iron syphon pipes, as already mentioned; but the minor ravines in the first 10 miles of the aqueduct are crossed by aqueduct bridges of iron. Besides a number of smaller ones there are five extensive

aqueduct bridges of this kind, one of which, near Culegarton, Plates 31 and 32, is shown in Figs. 16, 18, and 19, Plates 38 and 39. It consists of a wrought iron tube I, 8 feet broad and $6\frac{1}{2}$ feet high inside, extending over the deeper part of the ravines, supported at intervals of 50 feet by stone piers; and a cast iron trough J, also 8 feet broad and $6\frac{1}{2}$ feet high, supported on a dry stone rubble embankment at either end of the wrought iron tube I, extending over the remaining part of the valleys where the ground is not so much depressed. The bottom and sides of the wrought iron tube I are $\frac{3}{8}$ inch thick, and the top $\frac{7}{16}$ inch thick, the whole being strengthened by angle and T iron. The plates of the cast iron trough are $\frac{5}{8}$ inch thick, the dimensions of the largest being $4\frac{1}{2}$ feet by 4 feet, and they are connected and strengthened by flanges with rust joints. The level of the wrought iron tube I is about 3 feet lower than that of the cast iron troughs J J at each end, so as to ensure the tube being always completely filled with water up to the top, in order that the top of the tube may be kept always at the same temperature as the sides, and the tube may not be racked by the strain that would arise from the top plates becoming heated by the sun if the water were not in contact with them. In order to allow of emptying the tube at any time, for painting or other purposes, a discharge valve K, Figs. 18, 21, and 22, is provided at one end of the tube, by which the water can be run off into the valley beneath.

The junction between the wrought iron tube and the cast iron trough is shown in Figs. 21 and 22, Plates 40 and 41, and in detail enlarged in Figs. 23 and 24, Plate 42. It is made by bolting the cast iron trough to a cast iron bed-plate L, Figs. 21 and 23, and to upright cast iron standards M M, Figs. 22 and 24, at each side. The wrought iron tube rests upon a bolster of vulcanised india-rubber placed in a groove in the bed-plate L, Figs. 21 and 23, and projecting sufficiently above the surface of the plate to allow for the requisite compression on the india-rubber for making a water-tight joint by the weight of the tube bearing on it, without allowing the tube to come down to a bearing upon the bed-plate L itself. A similar india-rubber bolster is carried up each

side of the tube and compressed against it by oak wedges, the bolster and wedges being contained in a recess in the upright standards M M, as shown in Figs. 22 and 24. This arrangement leaves the wrought iron tube free to contract and expand longitudinally under change of temperature, without risk of leakage. The heads of all the rivets are countersunk for a short distance on each side of the bearing parts of the tube. The india-rubber bolsters are 2 inches diameter both at the bottom and sides of the tube. They are in separate pieces, the bolster under the bottom extending from the back of the wedge box M on one side to the back of the wedge box on the opposite side. The joints of the bolsters at the bottom corners are made by butting the bottom ends of the vertical bolsters upon the top of the transverse bottom bolster, the bottom ends of the vertical bolsters being slightly rounded out to fit the curvature of the bottom bolster. The side wedges are driven down tight on the ends of the bottom bolster. There are three oak wedges in each wedge box M, Fig. 24, Plate 42, with an oak feather or tongue let in to break the joints between the wedges and to guide the centre wedge while being driven down. A flat strip of india-rubber is placed between the back of the wedge box and the outermost wedge, as shown in Fig. 24. The wedges were carefully fitted before the feather grooves were made, and were put in with thick wet paint in the joints; the centre wedge was then driven down to tighten up the india-rubber bolster against the side of the tube. The spaces on either side of the wedges in the standards M are filled in with oakum and white lead.

The above construction of the iron aqueduct bridges was considered the most applicable in the first portion of the aqueduct, as no good building stone was to be obtained within any reasonable distance, and the roads were very badly suited for the carriage of materials. From the eleventh mile to the reservoir at Mugdock, however, good building stone was abundant; and all the aqueduct bridges in that district are therefore of stone. One of these, the Blairgar aqueduct bridge, is shown in Figs. 27 and 28, Plate 43, in elevation, longitudinal section, and plan; and Figs. 29 and 30, Plate 44, are transverse sections. There are in all 25 important

iron and stone bridges, some of them of considerable magnitude; and about 80 distinct tunnels varying in length from $1\frac{1}{2}$ mile downwards, and forming a total length of 13 miles. Where the aqueduct was formed in open cutting, the ground was filled in and the surface restored after the aqueduct was built, as shown in Fig. 15, Plate 37. At the cast iron troughs of the iron aqueduct bridges, and at the other bridges, the water way is covered with planking, as shown in the sections of the Blairgar aqueduct bridge, Plates 43 and 44, to prevent snow from choking the aqueduct. Grooves to receive stop planks are cut in the masonry of the aqueduct at intervals, and most of the bridges are provided with overflows and discharge sluices. The latter are similar in construction to the outlet sluices at the lochs, but of smaller dimensions.

The three valleys of the Duchray, the Endrick, and the Blane, Fig. 3, Plate 32, which are of great width and depth, the second being more than 2 miles wide, are passed by means of the 48 inch cast iron syphon pipes, carried down one side of the valley to the bottom, and up the opposite side. These pipes have the ordinary spigot and socket joints, a section of which is shown in Fig. 25, Plate 42, one quarter full size, the joint being made with lead N and yarn O. Some depressions on the line of these syphon pipes are crossed by flanged pipes supported upon stone piers 18 feet apart, as shown in Fig. 17, Plate 38, the joint being made by a ring of vulcanised india-rubber P, as shown by the section, Fig. 26, Plate 42, one quarter full size. In the Endrick valley two public roads and the Forth and Clyde Railway are crossed by these flanged pipes; and to support the pipes over these greater spans, cast iron brackets are put in, Fig. 17, Plate 38, abutting on the stone piers, which are thickened to receive them. The pipes are further strengthened at these places by projecting webs cast on them, as shown by the enlarged transverse section of the pipe, Fig. 20, Plate 39. It was found that the contraction and expansion of these long lengths of flange-jointed pipes under changes of temperature injuriously affected the spigot and socket lead joints at each end; and to obviate this, a felt covering about $\frac{3}{4}$ inch thick has been laid on all round the pipes, and protected from the weather by a tarpaulin cover laced tightly

over the whole. This has had the effect of almost entirely obviating the inconvenience that arose from contraction and expansion.

The service reservoir at Mugdock, Plates 31 and 32, has a water surface of 60 acres, and is 50 feet deep, the top water level being 312 feet above the level of the sea. It contains 548,000,000 gallons when full, equal to a supply for 29 days at the present rate of consumption; and thus admits of repairs being made upon the line of aqueduct without interrupting the supply to the city. The reservoir is entirely artificial, being formed by two earthen embankments 400 yards and 240 yards long respectively. The water is first received from the aqueduct into a basin at the upper end of the reservoir, from which it flows over four cast iron gauge plates, 10 feet long each, brought to a thin edge, into an upper pool or compartment of the reservoir having an area of about 2 acres. The depth of water passing over the gauge plates is regularly gauged, the delivery from the aqueduct thereby computed, and the quantity of water passing every day into Glasgow is thus known. From the upper pool the water passes into the main reservoir over similar cast iron gauge plates. The water is drawn from the reservoir by pipes laid in a tunnel cut through the rock in the solid, at the end of the main embankment, no pipes being laid through the embankments themselves. At the end of the tunnel next the reservoir there is a stand-pipe with valves at different heights, which admit of water being drawn off at various levels. The water passes down the stand-pipe and along a 48 inch pipe in the tunnel for a distance of about 50 yards to a circular straining well cut in the rock. Water can also be drawn direct from the aqueduct or from the upper compartment of the reservoir into the pipes leading to the city, without passing through the reservoir, by means of a line of 48 inch pipes laid through the bottom of the reservoir from the stand-pipe back to the upper end of the reservoir where the aqueduct enters.

The straining well is shown in vertical section in Figs. 31 and 32, Plates 45 and 46; and Fig. 33 is a sectional plan. The well is 40 feet diameter and 63 feet deep, cut out of the solid

rock. Within the straining well and forming an inner chamber of octagonal shape, 25 feet diameter, a series of oak frames Q Q are placed, covered with copper wire cloth of 40 meshes to the inch; these are held in the eight cast iron pillars R, which have grooves cast in them to receive the frames. These wire cloth strainers occupy only the lower part of the well, the space above being filled in with wood planking S S up to the top water level of the reservoir. The water passes from the outside through the wire cloth strainers into the inner chamber, and is taken off thence to the city by two lines of cast iron pipes 42 inches diameter, as shown by the arrows. The water undergoes no filtration, but in passing through these copper wire strainers any straws or other floating matters are separated from it. The pipes in the bottom of the straining well are provided with junctions and stop valves, as seen in the plan, Fig. 33, so as to admit of the supply being drawn direct from the reservoir while the strainers are being cleaned; which is done by emptying the well and throwing a jet of water upon the strainers from the inside outwards by a leather hose with the head pressure of the reservoir, the foul water being carried off by a tunnel through the rock. The frames Q Q carrying the strainers can also be raised to the top of the well and taken out for repairs, by being drawn up through the grooves in the cast iron pillars R in which they are fitted. The top of the straining well is roofed in and partly covered with glass, as a protection to the working gearing of the stop valves. These valves are each divided into two halves, affording together a water way of the full diameter of the 42 inch pipes. Each half of the valve is opened and shut by an iron rod passing up through a cast iron pipe, and terminating at a convenient height above the water level in a long brass nut, into which works a stationary iron screw, turned by a crank and bevil wheels.

The two lines of 42 inch pipes laid in the tunnel leading off from the straining well will deliver the whole 50 million gallons per day that the aqueduct is constructed to convey; but on emerging from the tunnel, which is 440 yards long, they are diminished to 36 inches diameter, and provision is made for additional pipes being laid when they may be required. At the point where the pipes are reduced to

36 inches diameter, a self-acting throttle valve is fixed on each line of pipes, the object of which is to shut off the water coming from the reservoir in the event of one of the pipes bursting or any other accident occurring whereby the velocity of the water in the pipe is increased beyond that to which the valves are adjusted. These self-acting throttle valves were suggested by Sir William G. Armstrong, and first used in the Manchester Water Works; and have been subsequently introduced in the Liverpool Water Works, (see Proceedings Inst. M. E., 1863, page 174.)

At intervals along the line of the mains to Glasgow and at several points in the city, stop valves are fixed in the large pipes, one of which for a 36 inch pipe is shown in Figs. 34 to 36, Plates 47 and 48. To admit of these valves being easily closed or opened, the slide is divided into two compartments T and U, one being considerably smaller than the other. The smaller slide T is the first opened, and the passage of the water through this opening so much reduces the pressure upon the larger slide U that it can also be opened with ease; the valve is thus easily worked by one man. To economise space, which is an object where large valves have to be placed in public streets, the total effective area of the valve has been reduced, in the case of these 36 inch valves, from 7 square feet, the area of the pipe, to $4\frac{1}{2}$ square feet; the smaller slide T having an area of 1 square foot, and the larger U an area of $3\frac{1}{2}$ square feet. To pass this contraction with the velocity that the water in the pipes will have when the discharge is greatest, the loss of head will be from 4 to 6 inches; but this loss is more than compensated for by the economy of the valve and the reduction in the dimensions of all the parts. The design of these valves is also due to Sir William G. Armstrong, and for large valves that have to be worked under great pressure they leave nothing further to be desired.

The concussion caused in large pipes by suddenly closing the stop valves requires to be guarded against, and this is done to a considerable extent by the construction of the stop valves themselves; but in order to reduce still further the risk from this cause, momentum valves are fixed on the pipes close to all the large stop

valves, and behind the self-acting throttle valves. They are simply safety valves constructed on the principle of the equilibrium or double-beat Cornish valve, and have been used both in the Manchester and Liverpool Water Works, (see *Proceedings Inst. M.E.*, 1863, page 175.) Air valves are placed upon all the summits and scouring cocks in the bottom of all the hollows on the mains. The scouring valves, as well as all the stop valves used in the city under 17 inches diameter, are the ordinary slide valves with double brass facings. The fire cocks used in Glasgow are of brass, upon the principle of the common ground cock, with the water admitted to the inside of the plug, which is hollow: the pressure of the water tends to force the plug into its seat, and thus to keep the cock tight. There are 2700 of these fire cocks in the city, placed at intervals varying from 40 to 60 yards; and also about 1200 fire cocks applied as cleansing cocks. The water meters used in Glasgow are those by Kennedy of Kilmarnock, of which there are upwards of 500 in use, producing a revenue of £15,000 a year, (see *Proceedings Inst. M.E.*, 1856, page 151.)

For the distribution of the water supply, the north part of the city is divided into a high and a low district. The high district is supplied by the 36 inch main from the Mugdock reservoir which is brought in by Maryhill, as shown at V in Fig. 2, Plate 31; and the low district by the main W brought in by the Great Western Road. These mains as well as the subsidiary mains in the city are connected at intervals, so that an accident occurring to any one section of the mains does not to any serious extent affect the general supply to the city. The large pipes only are connected; and each distributing pipe is furnished with a stop valve where it leaves the main, and a cleansing cock at the further end.

The quantity of water sent into the city from Loch Katrine during the first six months of the present year averaged 19,100,000 gallons per day; and 3,400,000 gallons per day in addition were sent in from the Gorbals Water Works on the south side of the river. Altogether therefore the total supply to Glasgow is 22,500,000 gallons a day, and this is distributed to a population of about 485,000 persons, being upwards of 45 gallons per head per

day. Of this quantity about $3\frac{1}{2}$ gallons per head per day is sold by meter.

The cost of the Loch Katrine Water Works has been as follows :—

Construction of Works	£761,000	
Land, parliamentary expenses, engineering, and sundries	157,000	
		<u>918,000</u>
Add sums annually payable to proprietors in the two previous water companies, capitalised at 4 per cent.	674,000	
		<u>674,000</u>
Total cost of the whole Water Works	£1,592,000	

The PRESIDENT remarked that the consumption of water in Glasgow as named in the paper, 45 gallons per head per day, appeared a very large quantity; and he enquired how much of that was supplied for public works and steam engines, &c., and how much was to be considered as the supply to dwelling houses for domestic purposes.

Mr. GALE replied that about $3\frac{1}{2}$ gallons per head was supplied by meter for trade purposes, and about another $3\frac{1}{2}$ gallons without meters for the same purposes, including steam engines, warehouses, shops, and all manufacturing and other purposes, except domestic use; making 7 gallons per head supplied for such purposes. That left 38 gallons per head as the supply to dwelling houses for domestic use, which was certainly a very large consumption, and no doubt much of it was due to waste.

Mr. E. A. COWPER enquired whether there were any turbines in use, driven by the water; for with the good pressure that was maintained in the mains, turbines could be used with great advantage in a large number of the manufactories of small size.

Mr. GALE replied that there were a few turbines of small power, but their consumption of water was included in the supply for steam engines and manufacturing purposes.

Mr. J. MANNING enquired whether the water used for watering the streets was included in the 7 gallons that were accounted for in the manner that had been explained.

Mr. GALE replied that the water on the streets was included in the 7 gallons supplied for the purposes of public works.

Mr. W. E. NEWTON considered it was a question of the greatest importance to the residents in large towns, whether the water was supplied to them by meter or otherwise. In London he understood the water companies could not be induced to supply by meter, giving as one reason that there was no meter they could use which would be fair both to themselves and the consumers; and the charge for the water was therefore fixed at 5 per cent. upon the rental of the house, irrespective of the quantity used: the same was the case also in many other large towns. This did not appear a fair and proper arrangement, since a house occupying an expensive situation in the

town had thus to pay much more for the water than a house on the outskirts, though the former might be using no more water or even not so much ; and he considered the only fair plan would be for each consumer to pay for the quantity actually used and no more. In Glasgow it appeared that only $3\frac{1}{2}$ gallons per head was supplied by meter out of the total daily consumption of 45 gallons, and he enquired how it was that only so small a quantity was supplied by meter, and whether the use of meters was optional with the consumers. He asked also what construction of meter was employed and how it was found to answer : if a really good meter were provided, it might be possible he thought to insist upon the water companies supplying by meter, instead of the present plan of charging irrespective of the quantity used.

Mr. GALE replied that the $3\frac{1}{2}$ gallons supplied by meter out of the daily consumption of 45 gallons per head was supplied to public works, and it was only for these purposes that the water was supplied by meter. Dwelling houses were not supplied by meter, but were rated according to rental, in the same manner as in London and elsewhere ; and he did not see how it could be arranged for the supply of water to dwelling houses to be by meter. The meters used were Kennedy's piston meters, which he had found continued to work correctly for a great length of time, and he considered them excellent meters.

The PRESIDENT thought the water company would be glad to supply the water by meter to all consumers, if it could be so arranged, but he feared the public in general would not agree to the universal adoption of any meter. The company had frequently found it necessary to threaten that if consumers did not take better care to prevent the waste of so much water, the use of meters would have to be made 'general and compulsory. He certainly considered the supply by meter was the only fair plan, so that each consumer should pay for the water he actually used.

Mr. J. FERNIE suggested that the cost of the meters would probably be a difficulty in the way of their general adoption : he enquired what would be the number required, and what was their cost.

Mr. GALE replied that there were upwards of 100,000 families supplied with water by the corporation within the area of distribution in Glasgow and neighbourhood, and the meters cost from £3 10s. to £10 each; so that the universal adoption of the meters would involve a very large outlay. In addition to this there was the further objection that one half the population of Glasgow drew their water from common taps, direct from the street main and common to twenty, thirty, or a hundred different families; and there was no means of properly apportioning the charge in such cases to the several parties.

The PRESIDENT suggested that the charge might be put upon the landlord in such cases, by a rate in proportion to the rental, the same as at present.

Mr. W. E. NEWTON observed that that was a difficulty not incidental to London and other large towns in England, because the houses were there all self-contained, and not in flats as in Glasgow.

Mr. T. SNOWDON enquired what was the amount of the water rate in Glasgow.

Mr. GALE replied that the rate was at present 1s. 2d. in the pound to all the district north of the Clyde, and 1s. in the pound on the south side of the river.

Mr. I. SMITH enquired what was the rate of charge for water supplied by meter to public works.

Mr. GALE replied that the charge by meter varied from 4·8d. to 7d. per 1000 gallons according to the quantity used, the smallest price being for a consumption exceeding 6,000,000 gallons per quarter of a year.

Mr. E. HUMPHRYS thought there was not so much objection to the use of water meters in London as appeared to be felt in Glasgow. At his own house in the neighbourhood of London the water was supplied by meter from the Kent Water Works, for which the charge was 10d. per 1000 gallons; and he had no reason to think that he paid for either more or less than the quantity actually used.

Mr. A. RIGG enquired whether the piston meters that were used would allow of the water ever passing through without being registered, or whether the working parts were so accessible that

the consumers might arrange them to pass the water without registering: and also whether the registration varied at all according to the pressure of water in the particular part of the town where the meter was situated.

Mr. GALE replied that the piston meters would allow the water to pass through occasionally without registering, when not in perfect order, which was an error in favour of the consumer; but they could not purposely be made to do so, except by damaging the meter. The registration of the piston meter was not affected by variation in the pressure of the water, but he thought meters constructed on the rotary principle would register different quantities according to the pressure.

Mr. W. E. NEWTON mentioned that a large prize had been offered by the London water companies for a really good and reliable water meter, from which it would appear they considered this still an important desideratum and were not fully satisfied with any of the present constructions of meters. One of the principal difficulties in ensuring correct registration arose he believed from the different pressures under which the meters were required to work in different situations.

Mr. E. A. COWPER observed that there were a great number of water meters at work in London, both piston meters and rotary meters, and he certainly thought some of them were practically reliable enough for all ordinary purposes. In a trial made about a year ago at Somerset House, with one of the piston meters and one of Siemens' rotary meters, measuring the water into a large square cast iron tank, it was found that the registration of the piston meter varied from 3 to 9 per cent. from the correct amount, according to the rate at which the water was passed through the meter; while the rotary meter varied only from $1\frac{1}{8}$ to $1\frac{3}{4}$ per cent. under the same change of circumstances. The range of variation in rate of working which the rotary meter admitted of was especially large, and it would measure at a much slower rate than a piston meter: in fact from as little as a wineglass full per minute up to 10 gallons per minute in the smallest size of meter, and from 100 to 100,000 gallons per minute in the larger sizes.

Water companies however were not favourable he thought to putting meters in private houses, because people would not pay so much for water as at present : for where the consumers had to pay for the water by a fixed charge, such as the rate upon rental, irrespective of the quantity used, they would not hesitate to use as much water as they wanted ; but if they had to pay by meter, according to the quantity used, and could save money by using less water, they would be very likely to do so, and in many cases would not use as much water as was desirable. It seemed fair to assume that the tenant of a house should use a reasonable quantity of water ; and therefore what was considered to be a fair average rate was charged, which he thought was on the whole the best way.

Glasgow was greatly to be congratulated he considered on having a supply of such excellent water, containing only $2\frac{1}{4}$ grains of soluble matter per gallon ; that was a most remarkable degree of purity, and was no doubt due to the almost entire absence of arable land in the drainage area from which the supply was derived, whereby the water was kept particularly free from any admixture of organic matter. The 72 square miles of drainage area was certainly a most ample extent of country for obtaining the water supply, and the storage capacity also appeared ample enough for Glasgow for the next century to come.

Mr. F. J. BRAMWELL enquired whether any difficulty had been experienced from the water acting upon lead pipes, on account of its exceeding purity.

Mr. GALE replied that, from careful investigations made before the water works were commenced, it was thought that under the ordinary circumstances of supply in Glasgow there would be no perceptible action upon lead pipes : and this had proved to be the case, as the water was not found to act upon lead to any perceptible or injurious extent.

Mr. H. MAUDSLAY observed that the area of passage for the water through the stop valves in the 36 inch mains appeared to be greatly reduced as compared with the size of the pipes ; and he enquired how it was that, if so large an area of passage as 7 square feet was required in the pipes, the area had been reduced to only

$4\frac{1}{2}$ square feet at the valves. The plan of dividing the stop valves into two parts, and opening the smaller slide first, so as to take off the pressure from the larger slide whilst that was being opened, was a simple and efficient way of getting over the difficulty of opening a large slide valve under a heavy pressure: the same object was sometimes accomplished by having a small pipe furnished with a cock, communicating with the main pipe on each side of the large valve, so as to relieve the pressure on the back of the valve at the time of opening or shutting it.

Mr. E. A. COWPER remarked that where it was desirable for the sake of convenience or economy to keep a valve small, it was reasonable to make the area of passage through the valve less than the area of the pipe: because the loss of head from the friction through a great length of pipe was very great, and therefore pipes were made as large as practicable; whereas the loss of head due to the water passing the contracted opening of the valve was but a small amount. For this reason it was a common practice to have valves or cocks smaller than the pipes connected to them.

Mr. GALE observed that there was an advantage in reducing the size of the stop valves in the mains, and so long as the area of passage was large enough to be effective, the smaller the valves were the better; since they were then more compact and more easily fixed in the streets, where the space available was often too small for fixing a large valve, on account of the street being already occupied by drains and other pipes for gas and water. In the stop valve shown in the drawings the area of passage of the 36 inch main was reduced about one third at the valve, and the loss of head in the water pressure caused by this was about 4 inches. If the contraction were in the form of a diaphragm with a hole in it, standing abruptly across the stream, the loss of head would be 6 inches; but by making the approaches to the valve slightly curved, the loss was reduced to probably not more than 4 inches of head. As the same amount of head would be lost by friction in a length of only about 50 yards of main, it was a mere trifle in comparison with the practical advantage of getting the stop valve so much smaller in size.

Mr. J. J. BIRCKEL remarked that a compound slide valve, having a small slide on the back of the main slide, had been in use many years for the steam regulators of many locomotive engines, for relieving the pressure on the back of the larger slide in opening the valve, in a similar manner to the double stop-valve that had been described. He enquired what was the pressure of the water in the mains in various parts of Glasgow.

Mr. GALE replied that there was great variation of level in Glasgow, from the sea level to 200 feet above sea level in the higher parts of the city and 300 feet above sea level at the Mugdock reservoir; and the pressure in the mains therefore varied correspondingly, ranging from 100 lbs. per square inch down to nothing. At Clarendon Place, St. George's Road, where the two mains from Mugdock reservoir met and the distribution to the city commenced, a series of gauges were erected on the several branches, to afford the means of observing the pressure, which varied in the mains of one district from 90 lbs. per square inch in the night to 70 lbs. in the day, and in the mains of the other district from 60 lbs. during the night to 40 lbs. during the day. In both of the mains the pressure could be increased a little if desired by opening the stop valves to the widest extent.

Mr. W. E. NEWTON enquired whether the water supply was constant, night and day, to all parts of the city, or whether cisterns were used; and whether any difficulty had been experienced from frost.

Mr. GALE replied that the supply was constant, night and day, without cisterns, except in the higher districts where cisterns were necessary. No difficulty whatever had been experienced from frost in the large pipes in the streets, but some trouble arose occasionally with the lead service pipes in houses, where they were not properly protected from the weather. With the ordinary precaution however of having the pipes properly protected, no difficulty from frost need be feared.

Mr. J. FERNIE observed that for crossing the three valleys of the Duchray, the Endrick, and the Blane, the cast iron syphon pipes employed were only 4 feet diameter, while the built and

tunnelled portion of the aqueduct was 8 feet square; and he enquired how the pipes were connected to the aqueduct at each end.

Mr. GALE explained that the aqueduct delivered the water into a small basin of about $22\frac{1}{2}$ feet by 15 feet, into which the 48 inch syphon pipe was inserted; and the other end of the pipe delivered the water into a similar basin on the other side of the valley where the aqueduct was renewed. The velocity of the water through the pipe was much greater than along the aqueduct, the fall in the aqueduct being 1 in 6336, while that between the two ends of the pipe was 1 in 1000.

The PRESIDENT enquired whether there had been any leakage at the ends of the Culegarton and similar wrought iron aqueduct bridges, where the junction of the cast iron trough with the wrought iron tube was made by the bolster of vulcanised india-rubber; and also whether there had been any trouble from freezing in the aqueduct.

Mr. GALE replied that no leakage had been experienced at the ends of the wrought iron aqueduct bridges, and the india-rubber bolster was found to make a perfectly water-tight joint, while allowing for the free expansion and contraction of the wrought iron tube. The water had never been found to freeze in the aqueduct, being covered over throughout the entire course of the aqueduct, excepting the open cast iron troughs.

Mr. J. E. SWINDELL enquired whether the geological formations met with along the line of the aqueduct from Loch Katrine to Glasgow presented a continuous and complete series according to the regular order.

Mr. GALE exhibited a series of specimens of the rocks passed through in the construction of the aqueduct. He explained that the Loch Katrine tunnel commenced in the lowest of the sedimentary rocks, after which came the mica schist and the clay slate. There was then a gap in the geological series at the commencement of the Clashmore tunnel, which passed through the conglomerate and the old red sandstone, and the red sandstone series was complete to the upper end, where it was thrown out by a great belt of amygdaloidal

trap at the Mugdock tunnel, causing a void ; and then the coal measures were met with at once, extending all the rest of the way to Glasgow.

The PRESIDENT enquired how rapidly the water level in Loch Katrine rose after a heavy rainfall.

Mr. GALE said he had known the water level rise as much as 12 inches in 24 hours when there had been a heavy fall of rain.

The PRESIDENT enquired what was the pressure at the lowest part of the 48 inch syphon pipes crossing the valleys.

Mr. GALE replied that the greatest pressure in the 48 inch pipes was 240 feet head, at the bottom of the Endrick valley, and that was the greatest pressure at any part of the course of the works.

Mr. A. RIGG asked what provision was made in the event of an accident, such as the bursting of one of the 48 inch pipes.

Mr. GALE said there were men constantly stationed for the purpose of shutting the water off in case of any accident, by means of sluice valves fixed at the aqueduct bridges, the water being discharged into the streams below, until orders could be sent to shut off the water at the Loch Katrine inlet.

The PRESIDENT enquired how often the straining well at Mugdock required cleaning, and whether much refuse was found in it at the time of cleaning.

Mr. GALE replied that the straining well was cleaned about once a week during summer and once a fortnight during winter. The refuse found upon the strainers consisted of leaves and bits of sticks and straws, and was sufficient to prevent the action of the strainers if allowed to go on longer, as the strainers were very fine and close, being made of copper wire cloth with 40 meshes to the inch.

The PRESIDENT proposed a vote of thanks to Mr. Gale for his paper, which was passed.

The following paper, by Mr. Andrew Duncan of Glasgow, Resident Engineer to the Clyde Trust, communicated through the President, was then read :—

ON THE CONSTRUCTION AND RESULTS OF WORKING OF THE LARGE STEAM DREDGERS ON THE CLYDE.

BY MR. ANDREW DUNCAN, OF GLASGOW.

The improvements in the channel of the river Clyde were commenced in 1770, under the direction of Mr. Goulbourne of Chester. At that time the navigable depth to Glasgow was only 3 feet at high water spring tides, as shown in the diagram, Fig. 7, Plate 52, with $1\frac{1}{2}$ feet at low water; while the high water of neap tides did not reach Glasgow at all. The river was crossed by seven fords, one being as far down the river as Dumbuck, about 12 miles below Glasgow, which had only 2 feet depth over it at low water. The first operation seems to have been the removal of the Dumbuck ford; and numerous cross jetties were afterwards shot out from either bank as far up as Glasgow, for the purpose of narrowing the channel, their outer ends being subsequently connected by parallel dykes. Soon after 1798 a few ploughs and a dredging machine worked by manual labour were employed in deepening the shallowest places; and the result of these operations was to enable vessels drawing 6 feet of water to come up to Glasgow at high water spring tides.

By the introduction of Steam Dredgers upon the Clyde, very important improvements have been effected in enlarging the channel of the river. In 1824 the first steam dredging machine was obtained, which now belongs to the town of Dumbarton, and is at work on the river Leven running out from the foot of Loch Lomond into the Clyde. By that time the Liverpool traders were coming up to Glasgow at high water spring tides, drawing 11 feet of water, as shown in the diagram, Fig. 8, Plate 52. In 1831, there were two vessels drawing 13 feet; in 1836, six vessels drawing 15 feet; in 1839, one drawing 17 feet; in 1853, two drawing 19 feet; in 1860, eight drawing 19 feet; and in 1863, two

vessels drawing 21 feet arrived at Glasgow, illustrated by the diagram, Fig. 9, Plate 52. The register tonnage of the vessels arriving and departing from Glasgow now exceeds three millions annually; and the minimum depth of the river is now not less than 12 feet at low water, with a rise of 9 feet at average spring tides and 7 feet at neap tides. The deepening and widening of the channel is still in progress, and more powerful machinery is in course of construction in order to hasten on the work. The depth which is now contemplated throughout the whole length of the river up to Glasgow is 15 feet at low water, giving 24 feet depth of high water at spring tides and 22 feet at neap tides.

As regards the deposit to be removed from the river bed, the greater portion of it comes from the drainage of the city, all the sewers of which discharge into the harbour, where the deposit lodges: also a considerable quantity of sand is brought down from the upper reaches of the river by the land floods, and lodges chiefly above Glasgow bridge. One of the two large double dredging machines is kept constantly at work in the harbour, the maintenance of which costs about £11,000 annually, and three fourths of this amount may be said to be due to city sewage.

The entire dredging plant of the river consists of two large double dredgers, shown in Plates 49 to 51, and three single dredgers, making five in all: connected with which there are 350 punts, each capable of carrying 8 cubic yards or 10 tons of material; one tug steamer of 80 horse power; and four screw hopper barges, each capable of carrying 300 tons, shown in Plates 54 and 55. During the last twenty years, 8,114,872 cubic yards or 10,143,590 tons of material have been removed by dredging; last year's work, ending June 1864, being 632,272 cubic yards or 790,340 tons.

The following is a general description of the two large double dredgers, Nos. 1 and 6, the latter of which is shown in Plates 49, 50, and 51.

The first double dredger, No. 1, was constructed in 1851 by Messrs. Murdoch Aitken and Co. of Glasgow. The hull is of iron, 98½ feet long, 31 feet broad, and 10 feet deep, drawing 5 feet of

water. The engine is a direct-acting marine engine, with cylinder 37 inches diameter and 3 feet stroke, and makes about 33 revolutions per minute. The boiler is a flue boiler with four furnaces, worked at a pressure of 4 lbs. above the atmosphere, and burning about 44 cwts. of coal per day of 10 hours. The bucket frames are of timber, trussed with iron rods, and the buckets can dredge in $22\frac{1}{2}$ feet depth of water. The buckets are 38 in number in each well, and each contains when quite full $3\frac{1}{2}$ cubic feet. The motion is communicated from the engine to the upper tumbler by cast iron shafting. The tumbler makes about $6\frac{1}{2}$ turns per minute, or 13 buckets per minute; but as the buckets are never quite full, the quantity lifted when working in good material is about 10 tons in 4 minutes, or about 2 cubic feet per bucket. Taking the year ending June 1864, the total quantity of material lifted by this dredger was 143,360 cubic yards or 179,200 tons; and as the total number of engine hours was 2483, the average quantity lifted per day of 10 hours was about 720 tons.

The material is discharged over the stern of this dredger, which arrangement was preferred to discharging at the sides inasmuch as less room is occupied in filling the punts by discharging over the stern; but this plan has the disadvantage of causing a loss of time while the punts are being shifted after each has been filled. Another disadvantage is that when working during flood tide in the lower reaches of the river, where the current is much stronger than in the harbour, the punts become nearly unmanageable, the current forcing them so hard against the stern of the dredger, which is always moored with its bow up-stream, as to render the shifting of the punts when filled a work of considerable labour; so much so in fact that working on the flood tide in the lower reaches of the river was avoided as much as possible.

The cost of this dredger was £8500. The crew required to work the dredger and punts consists of eighteen in all, namely:—captain, mate, engineer, fireman, bow craneman, sternman, wellman, two deckhands, cook, watchman, and seven men connected with the punts. The expenses of working during the year ending 30th June 1863 were:—

Wages	£916	19	2
Coals	204	10	7
Stores	73	11	5

Total working expenses	£1195	1	2
------------------------	-------	---	---

and the average annual cost of repairs is about £580.

The other large double dredger, No. 6, shown in Plates 49 to 51, was constructed in 1855 by Messrs. Thomas Wingate and Co. of Glasgow; and is arranged so as to discharge over the sides, in order to obviate the complaints brought against the previous dredger when working in the lower reaches of the river, for which this one was principally intended and is generally used. The crew required to work this dredger, exclusive of the crews on board the screw hopper barges, is twelve in all, namely:—captain, engineer, fireman, mate, cook, watchman, and six deckhands. Previous to the hopper barges being substituted for the small punts, this machine required a crew of twenty-one. The expenses of working during the year ending June 1863, the hopper barges being used, amounted to:—

Wages	£562	1	4
Coals	171	1	6
Stores	95	4	6

Total working expenses	£828	7	4
------------------------	------	---	---

The annual average cost of repairs is about £980, being considerably more than in the case of No. 1 dredger; for as the latter is working in soft soapy sludge, the buckets and links do not get cut up so soon as if working in sand, as in the case of No. 6.

Fig. 1, Plate 49, is a longitudinal section of No. 6 Dredger; and Fig. 2, Plate 50, a plan, showing the line of punts on each side of the dredger. Fig. 3, Plate 51, is a transverse section to a larger scale.

The dredger is built entirely of iron, and is 120 feet long and 33 feet broad, with a flat bottom and 5 feet draft of water; the plates are 7-16ths inch thick at the bottom and 5-16ths inch at the sides. The two boilers A A, Figs. 1 and 3, Plates 49 and 51, fixed in the centre of the vessel, are low pressure cylindrical flue boilers,

6 feet diameter and 15 feet long, working at 3 lbs. pressure above the atmosphere; and the coal consumed is about $2\frac{1}{2}$ tons per day of 10 hours. The engine B is a single side-lever condensing engine, with 37 inch cylinder and 3 feet stroke, running at an average speed of about 32 revolutions per minute, and driving the tumbler shafts C C of the two bucket frames D D at the reduced speed of 6 revolutions per minute, by two sets of spur gearing consisting of mortice wheels and cast iron pinions. Either set of buckets can be stopped and started independently of the other by means of clutch boxes worked by levers upon deck.

The power is communicated to the tumbler shafts C C through friction wheels E E, which are adjusted so as to transmit only a definite amount of power, and to slip round freely whenever the resistance exceeds that limit, from the buckets cutting too deeply into the ground or meeting with any obstacle: by this means any risk of damage to the machinery is prevented. One of these friction wheels is shown enlarged in Figs. 4 and 5, Plate 52. It consists of one ring revolving within another, the inner one F being keyed upon the shaft, and having a cylindrical recess of rectangular section turned in the circumference, $8\frac{1}{2}$ inches wide and 1 inch deep, in which fit a series of cast iron segment blocks I I. These are held in recesses in the outer ring G, and are each pressed against the inner ring by a set screw, adjusted to give the required amount of friction for driving the inner ring F and the gearing connected with it.

The bucket frames or dredging ladders D D, Plates 49 and 51, consist each of a pair of wrought iron plate girders, 77 feet long and 3 feet 9 inches deep in the centre, fixed parallel to each other with 2 feet 3 inches space between them, and stayed together by transverse plate stays. A transverse section of one of the bucket frames is shown in Fig. 6, Plate 52. These frames carry a series of cast iron rollers, upon which the bucket links travel; and a cast iron tumbler C and H, Fig. 1, at the top and bottom ends, over which the links work. Each ladder is suspended at the upper end by cast iron dead-eyes, firmly bolted to the main framing of the dredger; through these dead-eyes the upper tumbler shaft C passes freely, and round

them the ladder turns in being lifted or lowered: thus the upper tumbler shaft C does not bear any part of the weight of the ladder D. The shaft C is of wrought iron, and works in top and bottom brass bushes in pillow blocks bolted to the main framing of the dredger. Each ladder works in a vertical well K, Figs. 2 and 3, passing through the bottom of the vessel.

There are 41 buckets to each ladder, one of which is shown separately in Plate 53; Fig. 10 is a vertical section, Fig. 11 a plan of the back, and Figs. 12 and 13 transverse sections at the mouth and at the bottom. The buckets are constructed of 5-16ths inch wrought iron plates, bent and rivetted, with a flat back $\frac{1}{2}$ inch thick, upon which four wrought iron bars J J are rivetted, having eyes at the ends. These are connected together by the two intermediate links L L, 3 inches square, and jointed with $2\frac{1}{4}$ inch steeled pins, the whole forming a continuous chain with 2 feet pitch of the links. The pins are prevented from turning in the eyes of the bucket links J, which are not steeled, and the eyes of the intermediate links L are bushed with steel on the wearing side. In another dredger, No. 7, which is the most recent construction, the plan is adopted of inserting a bush of hard steel 5-8ths inch thick into the eyes of the single links L, while they are hot; and when worn this bush is driven out and another inserted, so that the eyes of the links do not wear at all. The mouth of the bucket is made $1\frac{1}{4}$ inch thick at the point, tapered to $\frac{1}{2}$ inch at the sides, and is faced on the outside with steel $\frac{1}{2}$ inch thick welded on the plate, as shown by the darker section in Figs. 10 and 12; the mouth is shaped in a projecting scoop form, for excavating and lifting the material dredged, as each bucket in succession passes under the bottom tumbler H of the ladder, Figs. 1 and 3.

The depth of excavation of the buckets is regulated by the lifting chain M, Fig. 1, Plate 49, attached to the lower end of the bucket frame D, and hoisted at the rate of about 26 feet per minute by the windlass or hoisting barrel N, which is driven by a small shaft from the engine through a clutch box and friction wheel, similar to those giving motion to the buckets and also worked

by a lever upon deck. The depth of dredging is continually gauged during work by a man stationed at the bucket well K holding a gauging rod resting on the river bottom, and having the lifting lever at hand and also a break handle for lowering the bucket frame, so as to keep the buckets constantly adjusted to a uniform depth of cut, according to the surface of the ground. A self-indicating gauge has also been fitted up on deck, so that the captain by glancing at the position of the bucket frame may in an instant tell at what depth below the surface of the water the points of the buckets are working. The greatest depth the dredger can work at is about 28 feet.

The forward motion for the cutting of the buckets is given by the bow chain O, Plates 49 and 50, which is 1 inch diameter, attached to a single-fluked anchor weighing 12 cwts. placed about 600 feet ahead of the dredger when at the commencement of a cut. The chain is hauled in with a slow motion by the windlass P, driven by a second small shaft from the engine through a clutch box and friction wheel, and having a set of change wheels for the purpose of regulating the rate of advance according to the nature of the material that is being excavated. This rate of advance varies from about $4\frac{1}{2}$ feet per minute in soft sand to $1\frac{1}{2}$ feet per minute in hard material. The dredging is done in parallel cuts of about 120 feet length. A corresponding windlass with two mooring chains R at the stern of the vessel gives the means of drawing back the dredger to commence a second line of excavation parallel to the former one; this windlass is driven by a small high pressure donkey engine with a pair of 12 inch cylinders, the dredging engine and machinery standing still during the time occupied in going astern, which is about 15 minutes, the speed being about 8 feet per minute. The two side warp lines S S, Fig. 2, extending from each side of the dredger, serve to steady it constantly during the progress of each cut, and to shift its position into the new line of excavation; they are worked by the surging heads T T, driven by the engine, or by hand power when required. The kedge anchors for these side warps are placed forwards of the dredger, so that the warp lines shall be somewhat in the position shown in the plan,

Fig. 2, when the dredger is at the commencement of a cut; the warps are also passed round leading blocks when required, since it is desirable they should be as nearly at right angles to the dredger as possible. The two warps on the side next the sailing channel of the river are lowered or slacked out when any vessel is passing, but are immediately tightened up again when the vessel has passed.

This dredger, No. 6, has now been at work for nine years, and has not required any repairs excepting for the wear and tear of the buckets, links, and rollers, and the usual repairs on the hull, &c. The upper tumbler however, having been found too low to allow of the shoot being placed at a sufficient height and slope for loading the large screw hopper barges, was raised $2\frac{1}{2}$ feet higher. The steeled mouths of the buckets last for the year's work of about nine months, when the buckets require to be thoroughly overhauled and put in repair. The pins and links of the bucket chains last generally about four months, and are replaced from time to time as required; a supply of duplicates being kept ready on board for the purpose. The rollers over which the buckets travel in ascending the dredging ladder are of cast iron, 1 inch thick in the barrel, with wrought iron spindles, having $1\frac{5}{8}$ inch journals laid with steel, which lasts about three months before being worn out; these run in small cast iron steps with hard wood caps, fixed on the top flange of the ladder, which are readily renewed when worn out, the cast iron bush lasting about two months, and the wood cap about nine months. Each bucket weighs $5\frac{1}{4}$ cwts., and the total weight of each set of buckets and links is about $7\frac{1}{4}$ cwts. The cubic content of each bucket is $3\frac{3}{4}$ cubic feet, and the average quantity of material brought up by each when working in sand is about 2 cubic feet. The number of buckets discharged per minute is 13 to 14 at the regular speed of about $6\frac{1}{2}$ revolutions per minute of the tumbler shaft.

The total quantity of material raised per day of 10 working hours varies very much according to the nature of the material dredged. Where the dredger No. 6 is at present working, about $1\frac{1}{4}$ mile below

the river Leven, the rate of working is 150 tons per hour of the engine; while in hard ground the quantity may perhaps be only one half of this. Taking the entire work performed by this machine during last year, namely 303,957 tons in 2680 engine hours, the average work for a day of 10 engine hours is 1134 tons, or $113\frac{1}{2}$ tons per hour. The total quantity of material lifted by the two large dredging machines Nos. 1 and 6 during the year ending 30th June 1864 amounts to 386,752 cubic yards, of which about 250,000 cubic yards may be considered as due to maintenance, and the remainder to the permanent widening and deepening of the channel.

The cost of dredging per cubic yard, taking the year ending 30th June 1863, as performed by No. 1 dredger, was as follows, the dredged material being conveyed away by the punts:—

Wages, coals, stores, repairs, and 5 per cent. interest	3·02	pence.
Repairs of punts	1·59	„
Towing punts to and from place of deposit	2·28	„
Discharging punts by wagons	12·29	„
Total cost of dredging per cubic yard . . .	<u>19·18</u>	„

The cost of dredging as performed by No. 6 dredger during the same period, with the screw hopper barges for carrying away the material, was as follows:—

Wages, coals, stores, repairs, and 5 per cent. interest	4·06	pence.
Discharging by hopper barges—	} . . .	2·30 „
Wages, coals, stores, repairs, and interest		
Total cost of dredging per cubic yard . . .	<u>6·36</u>	„

During this year No. 6 dredger was working near the two extreme ends of the river; and as during one half of the time it was attended by only two hopper barges in place of four, for discharging the material, much time was necessarily lost. This has since been rectified by the construction of additional barges.

The dredged material is disposed of according to two different modes. That filled into the 10 ton punts is towed down to some convenient part of the river, and discharged by barrows or wagons on to the banks or fields adjoining. That put into the screw hopper

barges, shown in Plates 54 and 55, is carried down to Loch Long, beyond the mouth of the Clyde, and deposited by opening the hopper doors U at the bottom of the carrying space W, as shown by the dotted lines in Plate 55. At the place where the deposit is made, the water is upwards of 200 feet deep, and the mouth of the loch is about 27 miles below Glasgow; the hopper barges at present at work contain each 300 tons of dredgings, and steam from 8 to 9 miles per hour. This latter mode is by far the most economical way of disposing of the dredged material, as seen by the above statement of the cost by the two methods; and the result has been so satisfactory that two additional barges are now being constructed, each to be capable of carrying 400 tons, making six barges in all. Fig. 15, Plate 55, shows the hopper barge being filled by the spout V from the dredger.

In conclusion it may be mentioned that a larger and more powerful single dredger, shown by the accompanying model, is now being constructed for the Clyde Trust by Messrs. A. and J. Inglis, of Glasgow. The dimensions of this dredger will be: extreme length 157 feet, extreme breadth 29 feet, depth 10 feet 9 inches, and bucket frame capable of working in upwards of 30 feet depth of water. The engine will be horizontal, with cylinder 44 inches diameter and adapted for a 3 feet stroke: the boiler will be tubular and capable of working to 25 lbs. pressure per square inch above the atmosphere. The buckets will be 39 in number, discharging over the side; the pitch of the bucket chain will be 30 inches, and each bucket when quite full will contain $13\frac{1}{2}$ cubic feet. The flat bucket back with the double links will be made of malleable cast iron with the links cast solid upon it: this construction has been found to last without requiring repair for more than double the time of the ordinary backs with rivetted links, shown in Plate 53. The bucket rollers will not require spindles, as they will have necks cast on the ends of the rollers, which will answer for the spindles. The lower tumbler shaft will be of wrought iron having strong rings or hoops at the journals, so that when worn the hoops can be easily removed and replaced. The only other difference of any consequence from the present dredgers will be in using grooved frictional gearing for

driving the hoisting barrel that lifts the dredging ladder, instead of spur gearing with a friction wheel as previously described. The total cost of the dredger will be about £17,000, and it is expected to be ready early in March next.

Specimens were exhibited of the dredger buckets and links, and the bucket rollers and bearings, &c., both new and worn out, together with samples of the material raised in dredging; and also models of the dredger and of the screw hopper barge.

Mr. W. SIMONS said he had built the screw hopper barges that were used in connection with the Clyde dredgers, and it was only within the last two years that they had been adopted: previously 350 of the square punts had been required to carry away the dredged material, but four of the barges now did the work of the 120 punts formerly attending one dredger. Each barge carried 300 tons, and was 120 feet long, 24 feet beam, and drew $8\frac{1}{2}$ feet of water when loaded; the engine was 40 horse power with 21 inches stroke, driving a screw 7 feet diameter, and the speed was the same whether loaded or empty, amounting to 9 miles per hour. The Clyde trustees contemplated abolishing the old punts altogether and employing only the screw hopper barges for removing the material dredged. The barges were loaded in about 70 minutes, and ran down the river and up Loch Long to a distance of about 50 miles from Glasgow, where the whole of the dredged material was discharged through the flap doors in the bottom. Hydraulic gearing was used to close and open the bottom flap doors in two of the barges, and in the others a common windlass had been applied, which had been found to work better. The total expenses of working the dredgers and barges were about £2 5s. per day, including wages, fuel, oil, and tallow; and the result of employing the screw hopper barges had been to reduce the cost of dredging from about 1s. per ton of material

when the punts were used to only 4*d.* per ton with the barges, making a saving of between £19,000 and £20,000 per annum.

By this system of dredging it might indeed be possible, he thought, to form an inland town into a seaport, such as Preston, Lancaster, Manchester, or Paris, where there was already an outlet into the sea for carrying away the dredged material; all that was required would be dredgers and barges of sufficient power and capacity for the quantity of work to be done, since the double dredgers now at work in the Clyde raised each about 1100 tons per day in regular continuous work, as stated in the paper. About the year 1800, when the depth of the river at Glasgow was only about 3 feet at high water, the annual revenue from ships coming up the Clyde was only £3320; but in 1825, when the river had been deepened by dredging to 12 feet, allowing vessels of 300 tons burthen to come up, the revenue had increased to £9000; while in 1863, with the depth increased to 22 feet at high water, the revenue amounted to £118,000, and the river was deep enough to float the "Black Prince" armour-plated frigate of 6000 tons burthen, built by the President, the largest ship that had yet been launched in the Clyde.

The PRESIDENT enquired how long it took to discharge the hopper barges through the bottom flap doors, and how the doors were arranged to be opened.

Mr. W. SIMONS replied that only 4 or 5 minutes were required to discharge the whole 300 or 320 tons of material carried by the hopper barge. There were twelve doors or six pair at the bottom, hinged to the iron hopper, and lined inside with timber; and the doors were let down for discharging by releasing the chains that held them up while the hopper was full. The chains passed over pulleys in the longitudinal iron girder which extended over the hopper from end to end.

The PRESIDENT enquired what part of Loch Long the material was deposited in.

Mr. W. SIMONS said the barges were not confined to Loch Long in particular for depositing the material, but might go to a greater distance from Glasgow if necessary. Loch Long had been chosen

because it was the deepest part of the channel near Glasgow, the depth being about 200 feet over a considerable portion of the loch, and the material could be deposited at any part of the loch.

Mr. W. E. NEWTON remarked that a dredging machine on a different principle had been used very successfully in different parts of the United States for many years, consisting of a large bucket fixed at the end of a long lever worked by chains; the bucket was lowered and dragged along the river bottom to fill it, and was then lifted by the lever, and swung round horizontally to the required position for discharging the stuff, which was let fall through a door in the bottom of the bucket into the barge beneath. The bucket raised about 26 cubic feet of soil at each stroke on an average. That appeared to him a simpler contrivance than the dredging machines ordinarily used in this country, such as those described in the present paper; it was at any rate much less expensive, and allowed of swinging the bucket round into any position required for discharging into the barge, whereas with the ordinary dredging machines the barge had to be brought to a particular place for receiving the stuff from the spout of the dredger. The gearing for working the lever was driven by a self-acting friction clutch somewhat similar to that described in the paper, except that in the American machine the inner or driving pulley was surrounded by a bridle provided with friction blocks, which were tightened against the pulley when running forwards, but slackened in running backwards; so that the clutch simply held on in working, and was not limited to slip when the resistance exceeded a certain amount, but would transmit the whole power of the driving machinery, its only purpose being to avoid breakage from sudden jerks and to release itself for running backwards. He had seen a machine on that principle, known as the "American excavator," used experimentally some years ago on the Eastern Counties Railway in the neighbourhood of Brentwood, for excavating a cutting, and all the gearing in it was worked with friction clutches of the same kind. That description of clutch was indeed much used in America for all sorts of machinery, and was found very economical and effective in preventing breakages, by allowing the

gearing to yield under any undue strain. He had never known it fail in transmitting the full driving power, and thought it would have some advantage over the friction wheel described in the paper.

Mr. H. MAUDSLAY enquired whether the friction wheel in the dredger described in the paper was found effectual in work, by always slipping whenever the buckets came into too hard ground or took too deep a scoop into the soil, or met with any other obstruction.

The SECRETARY said he had seen the dredger at work in the Clyde, and the friction wheel was found to answer its purpose thoroughly. The screws of the friction blocks were adjusted originally to the pressure required for the ordinary working, and then continued unaltered, without requiring any further attention in working. He had seen the bucket frame lowered slightly below the proper working position, causing the buckets to bite gradually deeper in the bed of the river, until the resistance was just sufficient to overcome the friction of the blocks, when the buckets stopped while the driving pulley or ring continued to revolve outside the friction wheel; but on slowly raising the bucket frame again, the friction wheel gradually started again as the resistance diminished, and the whole worked with complete smoothness and readiness. The engineer working the dredger stated that the friction wheel had given no trouble, and there had not been any difficulty in keeping it adjusted exactly to the point desired for working. The same kind of friction clutch was also applied to the lifting gearing by which the end of the bucket frame was raised and lowered; so that all portions of the machinery were started and stopped quite gradually, the friction gear being continually called into action to meet the irregularities in the level and material of the bed of the river and prevent any straining of the machinery.

Mr. J. SHEPHERD asked whether the material raised by the dredgers was used for agricultural purposes, as a manure, and whether it had any commercial value for such purposes, since it appeared the sewage of Glasgow was all discharged into the Clyde and would therefore be deposited in the bed of the river.

The PRESIDENT replied that the quantity of sewage matter deposited in the river bed formed so very small a proportion of the quantity of material raised by the dredgers, that it had never been thought to apply it as a manure, and it had no commercial value for such a purpose.

In reference to the American dredger that had been referred to, a somewhat similar apparatus was occasionally used on the Clyde at the present time in dredging alongside the wharfs in the harbour, consisting of a rake or plough fixed on the end of a long pole, which was worked from the bank by a number of men, or from a punt on the river, and was moved along the edge of the wharfs for clearing out the material from the face of the quay and removing it within reach of the dredger, in cases where the dredger could not be conveniently worked close alongside.

Mr. J. J. BIRCKEL observed that the depth of 13 feet at low water in the Clyde at Glasgow and 22 feet at high water would give a tidal fall of only 9 feet; and he enquired whether that was the actual tidal fall at Glasgow, since at Liverpool, on the same coast, the tidal fall was as much as 32 feet. He asked also whether there was not a risk of some portion of the material deposited in Loch Long being brought back into the river by the tides, as the loch was so close to the mouth of the Clyde: in the case of the Mersey no deposit was allowed to be made at any part of the approaches to the river, for fear of interfering with the channel.

The PRESIDENT explained that there were so many arms of the sea to fill near the mouth of the Clyde, and so many bends in the river itself, that the tidal wave did not come up to Glasgow in the same quantity as in the Mersey; and the rise and fall at Glasgow averaged therefore from 7 to 9 feet only, very seldom more. Loch Long was a blind arm of the sea, with no outlet at the further end, and no navigation through it, and there was very little tide in it: and as it was about 200 feet deep where the barges were discharged, there did not appear any probability of any portion of the deposit being carried back by the tide.

From the paper that had been read it was obvious that the dredging machines employed in the Clyde had been productive of

very remarkable advantages to Glasgow. From a depth of water of only about 3 feet at the beginning of the present century, the river bed had now been deepened to about 22 feet at Glasgow at high water within the space of about 63 years. But it was since the introduction of steam navigation into the Clyde that the greatest part of this improvement had taken place. The steam tugs drawing vessels up and down the river first led to the rapid deepening of the bed by dredging ; and then the increase of revenue arising from the larger burthen of the vessels trading to Glasgow afforded the means of increased expenditure upon the dredging operations : thus both the depth of the river and the advantages to the city went on increasing simultaneously.

He moved a vote of thanks to Mr. Duncan for his paper, which was passed.

The following paper was then read :—

ON THE WORKING AND CAPACITY OF BLAST FURNACES.

By MR. CHARLES COCHRANE, OF DUDLEY.

At a former meeting of this Institution in 1860 the writer read a paper on a method of taking off the gas from a close-topped blast furnace at the Ormesby Iron Works, Middlesbrough (see *Proceedings Inst. M.E.*, 1860, page 121); and the original construction of closed top and lifting valve for charging is shown in the accompanying Fig. 1, Plate 56, the materials for the charges being filled into the exterior space B surrounding the charging valve A, which is drawn up into the position shown by the dotted lines for allowing the materials to fall into the furnace; while the gas is taken off from the furnace top by the passage E.

The usual plan of closed top adopted in blast furnaces is that represented in Fig. 3, Plate 58, in which it will be seen that the materials are filled in against a lowering cone C, placed in the throat of the furnace, which on being lowered into the position shown dotted permits their fall into the furnace. The tendency of the material in this case is to roll outwards from the charging cone to the side of the furnace, and thence back again to the centre, as shown in the drawing.

It was thought at the time of adopting the plan shown in Fig. 1, Plate 56, that the height of the materials carried by the same furnace would be increased, and that a corresponding economy in consumption of fuel would result, owing to the circumstance that where the plan shown in Fig. 3 is adopted the level of the materials must always be maintained at a certain distance below the top, to ensure the fall of the cone C at charging time. The plan shown in Fig. 1 was devised with due regard, as it was thought, to the arrangement of the materials in the furnace; and it was

intended that they should arrange themselves as shown by the dotted line in that drawing, part of the larger material rolling to the outside of the furnace and part to the centre.

As long as the furnace could be kept so full as to ensure the arrangement of materials shown by the dotted line in Fig. 1, there was no reason that it should not work uniformly; but the practical result was that it was found impossible to keep the furnace sufficiently full to secure the distribution of the materials in the manner intended. The level of the surface of the materials was generally below that intended, the consequence of which was that the material on falling into the furnace was shot into the centre, from whence the largest pieces rolled outwards, and the whole charge arranged itself as shown by the full line in Fig. 1. The result of this was irregular working of the furnace over a period of many months, during which an explanation of the irregularity was in vain sought for. At one time it was thought the back pressure of the escaping gas had something to do with the irregularity; at another the cause was sought for in the difficulty of keeping the hopper valve A of the furnace tight, and the necessity for using small material around the valve as a kind of lute between every charge to prevent the escape of the gas: until it occurred to the writer that the arrangement of the materials in the furnace was the sole explanation of the difficulty, and that as all the material was shot into the centre of the furnace the small pieces would remain there whilst the large would roll to the outside. Believing that it was of great importance, in order to secure uniform results, that there should be a uniform distribution of the heated gas from the hearth over the entire horizontal area of the furnace at each stage of its height, he considered that the effect of any small material being collected in any portion of the area would be to obstruct the passage of the gas at that part, and so prevent that portion of the material from being heated to its proper degree of temperature.

Deeming this to be the explanation of the irregularities experienced in the working of the furnace, the writer devised a method of distributing the material so as to prevent such a result,

by the introduction of a frustum of a cone D, Fig. 2, Plate 57, suspended inside the throat of the furnace, which was found to be all that was necessary. The materials then arranged themselves in the desired manner, as shown in the drawing; and the result has since been a perfect uniformity in the working of the furnace. Where previously a yield of foundry iron from the same furnace could not be relied upon for more than about 24 hours at a time, and the annoyance was incurred of the furnace suddenly changing to white iron, the production of white iron except when desired is now unknown. A consideration of these facts will lead to a fair estimate of the importance of the arrangement of the materials in a blast furnace. Anything that opposes the free passage of the ascending heated gas at any part of the furnace must direct the gas into another channel, and the material thus left insufficiently acted upon finds its way into the hearth at a low temperature, and white iron is the result.

The effect produced on the distribution of material by this internal frustum of a cone is obviously similar to that of the ordinary lowering cone when lowered, shown in Fig. 3, Plate 58; and the latter has now consequently been finally adopted at the Ormesby Iron Works as the permanent form of the arrangement, and is now being carried out there.

The most perfect action of a blast furnace the writer conceives to consist in the development of the highest temperature needed for the production of the required quality of iron, in a layer or stratum as little removed from the tuyeres as possible; and the gradual absorption of the heat from the ascending gas by the materials through which it passes, until it leaves the throat of the furnace at the lowest possible temperature. Anything which tends to cause a more perfect absorption of the heat developed in the hearth, or to lower the level of the region of highest temperature in the furnace, will thus be beneficial.

With regard to the absorption of the heat from the gas, it is obvious that the hotter the temperature at which the gas escapes, the more wasteful must be the effect; and theoretically the height

of a furnace should be increased until the temperature of the escaping gas is reduced to that of the materials on their introduction into the furnace top. This is the theoretical limit to the height of a blast furnace: but it must not be forgotten that the less the difference in temperature between two bodies, the less rapid is the communication of heat from the hotter to the cooler; hence for the absorption of the last few degrees of temperature from the ascending gas a much greater height of material is necessary than where the gas and the material differ more widely in temperature. Already with 50 to 60 feet height of blast furnace in the Middlesbrough district the temperature of the escaping gas does not exceed 500° to 600° Fahr.; and it is a question to be answered only by experiment how far the gain from the heights of 70 to 75 feet already accomplished at Middlesbrough, and further heights of 10 or 20 feet additional that are contemplated, will compensate for the extra work in raising the materials to the additional height and for the more substantial plant required. In the direction of height there is unquestionably on this account a limit which will speedily be attained: supposing the limit be not previously determined by the necessity for increased pressure of blast and by the increased difficulty in working the furnaces.

As regards the benefit produced in the working of a furnace by lowering the level of the region of highest temperature, it is evident that this benefit is of the same nature as in the previous case, since the lowering of that level is equivalent to an increase in the height of the furnace. The level of the region of highest temperature is dependent upon the heat of the blast, and is brought down nearer to the tuyeres only by using a hotter blast: and in the writer's opinion the chief source of economy yet to be attained in the working of blast furnaces, independent of the more extended application of the waste gas, lies in the use of blast heated to a still higher temperature than that hitherto known. The yield of iron from any ironstone is governed by the percentage of iron it contains, and the consumption of limestone by the nature of the ironstone; and both these are therefore fixed quantities for the special materials employed. But that is not the case with the coke, which

offers a fruitful source of saving; and in what way therefore this saving is effected by increased temperature of the blast becomes a most important question, involving as it does the general theory of hot blast.

It appears to the writer that in order to explain the effect of the hot blast it is necessary to regard the nitrogen of the atmosphere and the generated carbonic oxide as the great heat "carriers" in the operations of the blast furnace. This consideration involves two others: namely the time required for heating the nitrogen from its initial temperature at entering the furnace up to that needed for the fusion of the materials in the furnace; and also the method by which the gases are heated. Taking it for granted that the colder and consequently the denser pure oxygen is the more intense is the combustion of any body burning in it, there is evidently no necessity for heating this constituent of the atmosphere. It is further obvious that supposing 3000° Fahr. be the temperature required for the fusion of the materials on their reaching the hearth, then every pound of the nitrogen introduced by the blast must be raised to that temperature before the fusion can take place.

Now in a cold-blast furnace the nitrogen is introduced at the lowest temperature, and requires necessarily the longest time for being raised to the requisite temperature: hence the maximum temperature in the furnace is produced at a higher level, and diffused over a larger portion of the furnace where it is not wanted; and it is consequently impossible in some cases ever to get the temperature sufficiently high at any part of the furnace to produce more than the qualities of iron known as forge iron. In proof of this may be mentioned an attempt made some years ago at the Ormesby Iron Works, Middlesbrough, to produce cold-blast iron of a gray or foundry quality. It was in vain however that the burden of ironstone was reduced, that is the proportion of coke increased: the temperature of the hearth could not be sufficiently raised to produce any other quality than forge iron, the effect of the reduced burden being only to throw an increased temperature into higher regions of the furnace. The attempt was consequently

abandoned; not however until it became obvious that the burden might have been still further diminished with only the effect of diffusing the hottest temperature into still higher regions of the furnace.

Whatever heat is imparted to the nitrogen of the atmosphere and also to the carbonic oxide generated in the furnace is of course delivered up again to the materials in the furnace, excepting only the portion lost by the temperature at which the gas escapes at the throat of the furnace. The effect of heating the nitrogen before its entrance into the furnace now becomes more clear. It has a shorter distance to travel up within the furnace before the maximum temperature is attained, for the simple reason that, having been partly heated already, it requires less time to become further heated to the temperature required in the furnace, having got the start by the amount of its initial temperature. Hence the fusing heat is generated nearer to the tuyeres; and this circumstance, together with the smaller expansion of hot blast compared with cold blast on entering the furnace, seems to furnish a satisfactory explanation of the more immediate effect of heated air in preventing diffusion within the furnace of the region of highest temperature.

As to the method of heating the nitrogen, it must be borne in mind that the heat generated in a blast furnace is obtained wholly or nearly so by the imperfect combustion of the carbon of the coke into carbonic oxide as the final result, a process by which theoretically only about one fourth the total quantity of heat is developed that would be obtained by the perfect combustion of the same carbon into carbonic acid, showing a loss in the fuel of about 75 per cent. of heat; since 1 lb. of carbon burnt into carbonic oxide develops only 2880 units of heat, whilst 1 lb. of carbon burnt into carbonic acid develops about 11700 units of heat. For although the combustion of the carbon of the coke in the blast furnace is partially or wholly into carbonic acid so long as the supply of oxygen is in excess, this condition applies only to the lower portion of the furnace nearest the tuyeres; and this carbonic acid becomes ultimately reduced to carbonic oxide by passing through the excess of carbon in the mass of incandescent coke

occupying the upper portion of the furnace. If therefore the nitrogen be heated partially or wholly before entering the furnace, by any means involving the perfect combustion of the fuel employed into carbonic acid, it follows that a large saving in fuel must necessarily result; and to give an idea of the real influence of the nitrogen of the atmosphere on the consumption of fuel in the blast furnace, the writer has endeavoured to express numerically the effects produced by taking three different cases of the blast entering the furnace at the various temperatures of 50° , 650° , and 1150° Fahr. respectively. It is assumed that the air has to be heated within the furnace to 3000° Fahr. in each case; that 1 lb. of carbon burnt into carbonic oxide will develop 2880 units of heat, that is, will raise 2880 lbs. of water through 1° Fahr.; and that the specific heat of air is $\cdot 275$, compared with that of water as 1.000. It is further assumed that 4500 cubic feet of blast enter the furnace per minute; and as 1000 cubic feet weigh 76 lbs., the weight of blast entering the furnace per minute will be 342 lbs., 77 per cent. of which or 263 lbs. weight is nitrogen.

In the three cases cited it will be seen that the work to be done within the furnace is to raise the temperature of the air through

2950° in the first case,

2350° in the second,

1850° in the third.

In the first case, namely to heat 263 lbs. of nitrogen through 2950° , there will be required

$$\frac{263 \times 2950 \times \cdot 275}{2880} = 74 \text{ lbs. of carbon per minute.}$$

In the second case, namely to heat 263 lbs. of nitrogen through 2350° , there will be required

$$\frac{263 \times 2350 \times \cdot 275}{2880} = 59 \text{ lbs. of carbon per minute.}$$

In the third case, namely to heat 263 lbs. of nitrogen through 1850° , there will be required

$$\frac{263 \times 1850 \times \cdot 275}{2880} = 46 \text{ lbs. of carbon per minute.}$$

These results show that to raise the temperature of the blast from 50° to 650° before it enters the furnace causes a saving in the blast furnace of 15 lbs. of coke out of 74, or about 20 per cent.; and that a further increase of temperature from 650° to 1150° occasions a saving of 13 lbs. out of 59, or about 22 per cent. To show that these calculations are not so merely theoretical as might at first be supposed, it may be here stated that in the writer's experience the raising of the temperature of the blast from 650° to 1150° at the Ormesby Iron Works has accomplished an actual saving of from 17 to 18 per cent. of coke in the blast furnace; and this was effected at an expense of coal outside the furnace of about one half the weight of coke saved within the furnace. The writer believes however that, were it in his power to compare two exactly similar systems of hot-air stoves, the additional fuel consumed outside the furnace would approximate more nearly to one third of the weight saved inside the furnace than to one half. But the difficulty of having to compare the ordinary cast iron stoves with the regenerative hot-blast stoves, by which the highest named temperature of 1150° is attained, is too great to allow of the comparison being made more precisely.

In the cold-blast furnace the method of heating the air is simply by its direct contact with the heated material and incandescent coke, and it is heated altogether at the expense of carbon burnt only into carbonic oxide instead of into carbonic acid. In the hot-blast furnace, by the more complete combustion of the heating fuel in the hot-blast stoves, exterior to the furnace, the nitrogen is heated not only at a cost of fuel represented by a saving of theoretically three fourths in the actual weight of coke required within the furnace to raise the nitrogen to the same temperature, but also with the further advantage that instead of burning coke it is coal that is used for the purpose. In other words, for every pound of coal economically burnt outside the furnace in raising the temperature of the blast, three pounds of coke will be saved within the furnace, whether the furnace be open or closed at the top.

It may be thought that a comparison made between an open-topped furnace where the gas burns freely as it escapes, and a

close-topped furnace where no such combustion takes place, is not a fair one; and that the combustion of the gas at the throat of the open-topped furnace, by imparting heat to the materials at the throat of the furnace, would tell in favour of the consumption of fuel in the open-topped furnace. But facts speak otherwise, and it appears that there is practically no difference whatever due to this cause.

It will thus be seen that a definite limit to the height of a furnace is soon reached in practice; and that the advantage derived from increasing the actual height of a furnace may be partly secured by increasing the temperature of the blast, and thereby lowering the region of maximum temperature in the furnace.

The only question that remains is as to the diameter of the furnace. In reference to this dimension, the danger that has been alluded to from the formation of cold masses in the centre of a blast furnace serves as a caution against the more dangerous formation of cold masses attached to the sides of the furnace, technically called scaffoldings. It is obvious that, if the width of the boshes of a furnace be large in proportion to the height and the volume of the ascending gas, there will be a tendency to unequal diffusion of the heat imparted by that gas over the successive horizontal sections of the furnace, and irregularities in its working will consequently set in. There is then a limit to the diameter of the boshes, the largest of which yet in use is believed to be about 21 feet; beyond this size it appears very questionable whether any beneficial result would arise, though a furnace has been stated to be in course of construction at Cwm Celyn having a diameter of 24 feet at the boshes.

The nature of the materials of the charge in any contemplated increase of the dimensions of a blast furnace must be most scrupulously borne in mind. The density of the coke is the most important consideration; but next to that is the friability of the ironstone itself. In the Staffordshire district it would be useless to build furnaces of the height contemplated and actually employed in the Middlesbrough district, for the simple reason that the

Staffordshire coke is friable and would be crushed most injuriously by the weight of superimposed material.

It is thus evident that the actual dimensions of a blast furnace in any particular instance are much dependent upon special local circumstances; but the writer has endeavoured to point out the general principles which guide the determination of the dimensions to be adopted.

The PRESIDENT thought the paper that had been read was an excellent one and gave a clear explanation of the advantage of hot blast and the principles involved in the arrangement of the materials in a blast furnace. He enquired what had been found to be the effect of the internal distributing cone in the throat of the furnace at the Ormesby Iron Works, as regarded the quality of the iron produced, and whether there had been any difficulty in keeping the furnace up to the desired quality of foundry iron since the internal cone had been added.

Mr. COCHRANE replied that the quality of the iron now made by the furnace was the same as the foundry iron made in the same furnace before the internal distributing cone was added; but the difference produced by the cone was this: that before its application, although the furnace would make as good a quality of foundry iron when in good working order, it was liable continually to be thrown suddenly to white iron, owing to irregularities in the arrangement of the materials in the furnace, causing them to reach the hearth in an imperfect state of fusion, so that white iron was produced notwithstanding the burden was the proper one for foundry iron; whereas since the addition of the internal cone no white iron had ever been produced with a foundry iron burden, but the furnace was now kept regularly to foundry iron without any irregularities occurring in its working.

The PRESIDENT enquired what was the construction and weight of the internal cone, and what was found to be its durability in that situation.

Mr. COCHRANE replied that the cone was made of sheet iron and was suspended inside the throat of the furnace by four chains from the charging plate, as shown in the drawing; its weight was about 5 cwts. The cone had now been in regular use for about four months, and would probably have lasted ten or twelve months before requiring renewal, if that plan of charging had been continued in constant work; it was however only a temporary construction which he had adopted by way of trial, for the purpose of satisfying himself respecting the arrangement of the materials in the furnace top; and the entire furnace top was now in process of alteration to the ordinary plan of closed top with the cast iron lowering cone for charging, as shown in Fig. 3, Plate 58, since this served the same purpose of distributing the materials in the furnace as the internal distributing cone; a single large opening was also employed for taking off the gas at one side, instead of the annular gas chamber previously used.

Mr. J. E. SWINDELL enquired how the impossibility of making No. 1 foundry iron with cold blast in the Middlesbrough district was accounted for, and whether it was considered due to the more intractable nature of the materials in that district.

Mr. COCHRANE believed it was entirely owing to the more intractable nature of the materials that it was impossible to make the best qualities of foundry iron with cold blast in the Middlesbrough district, because in Staffordshire No. 1 foundry iron could be produced with cold blast. The explanation he thought was as submitted in the paper just read: that with cold blast the air had to travel higher up into the furnace before a sufficient heat was obtained for the reduction of the iron ore; and it was possible also that the nature of the materials in the Middlesbrough district required a temperature which could not be produced at all with cold blast.

Mr. J. E. SWINDELL asked whether it was considered that the materials in the furnace really did melt nearer to the tuyeres with

hot blast than with cold blast; he understood that practical men who had worked both hot and cold-blast furnaces stated distinctly that the materials melted nearer to the tuyeres in a cold-blast furnace than with hot blast.

Mr. COCHRANE said the object to be aimed at in the blast furnace was to get the region of maximum temperature limited as much as possible in its extent above the tuyeres, and to leave all possible height of the furnace available for the absorption of the heat generated in the lower parts. No doubt with cold blast the materials were melting as close to the tuyeres as with hot blast, but the objection to the cold blast was that it caused them to be melting also considerably above the tuyeres, for a height of probably as much as 10 or 12 feet above. The object more correctly stated was therefore to bring down, not the point at which the materials *did* melt, but the point at which they *did not* melt; that is, to bring down the upper limit of the region of fusion, and confine the maximum temperature to the least possible height above the tuyeres: and he was fully satisfied that this was the effect produced by the hot blast as compared with the cold blast.

Mr. E. REYNOLDS suggested that the difficulties which had been met with in the working of the furnace arose from the construction of the closed top and charging valve, which appeared to be a reversing of the old mode still employed at the Butterley Iron Works, where the charging was done by means of a filling barrow, which carried the charge in a bucket at the end of a projecting arm reaching over the centre of the open top of the furnaces; each bucket consisted of a vertical cylinder, the bottom of which was closed by a cone held up against it, and the charge was dropped into the furnace by lowering the cone valve. By that plan, when the cone was lowered for charging, the tendency of the charge was to shoot outwards; but with the construction of the closed top shown in the drawings, when the charging valve was raised, the slope of the charging plate surrounding the valve would cause the material to be shot towards the centre of the furnace, and would thus occasion the difficulties that had been experienced. These he suggested might be obviated if the sides of the charging plate

were more nearly vertical, so as to shoot the material less into the centre of the furnace, and agree more nearly with the vertical sides of the charging cylinders in the old plan used at Butterley.

Mr. COCHRANE did not see how such an arrangement of the charging plate could have been carried out with the construction of charging valve that had been employed at the Ormesby Iron Works, nor was the slope of the charging plate a point of importance after the internal distributing cone had been added. The object of having a charging valve that should be raised for charging, in place of the ordinary cone valve that was lowered in the furnace at each charge, had been to save as much height as possible in the furnace and admit of keeping the materials charged up to a higher level in the throat of the furnace. It had been a question therefore in the first instance between employing a much larger charging valve, so as to avoid all risk of the charges being shot into the centre of the furnace; or keeping the size of the valve as small as was compatible with maintaining the level of the materials in the furnace up to the full height intended: and it had been found, as the result of experience, that the original size of the charging valve, only 6 ft. 6 ins. diameter, was too small to prevent the charges falling into the centre of the furnace, although the difficulties arising from that cause had since been entirely obviated by the addition of the internal distributing cone for directing the materials outwards towards the sides of the furnace. At a neighbouring furnace however in the Middlesbrough district, where the same construction of closed top with lifting valve had been adopted, the valve had been made 9 ft. 6 ins. diameter instead of only 6 ft. 6 ins.; and the consequence of this increase in its size was that the charges were distributed sufficiently towards the sides of the furnace, instead of shooting into the centre, and the furnace was working admirably without any need of an internal distributing cone such as it had been necessary to have recourse to in the furnace described in the paper.

The PRESIDENT enquired what was the difference of size in the Staffordshire blast furnaces as compared with those in the Middlesbrough district.

Mr. J. E. SWINDELL said that the furnaces in the Staffordshire district were from 13 to 18 feet in diameter as a maximum, and not exceeding 45 to 50 feet in height.

The PRESIDENT asked whether the materials of the charges for the close-topped furnace described in the paper were broken to any particular size before charging.

Mr. COCHRANE replied that the limestone was broken by hand labour to a size of about 4 to 6 inches cube; but the ironstone was taken as it came from the kilns, and no attempt was made to break it at all, as that had not been found to pay.

The PRESIDENT enquired whether the high temperature of 1150° Fahr., which had been mentioned as the heat of the hot blast at the Ormesby furnace, was the average temperature of the blast, and what was the extent of fluctuation in the temperature.

Mr. COCHRANE replied that the blast was heated by means of Mr. Cowper's regenerative hot-blast stoves, and the average temperature of blast obtained was 1150° in regular working. The very outside fluctuation was about 200° during the four hours that each stove alternately heated the blast, the maximum temperature being nearly 1250° when the newly heated stove was first turned on, and the minimum temperature not less than 1050° at the end of the four hours' working of the same stove.

The PRESIDENT asked what had been the experience with reference to the durability of the regenerative hot-blast stoves, and whether any difficulty had occurred with any part of them.

Mr. COCHRANE said he had now had these stoves in regular work for upwards of three years, and as regarded their durability they did not show the slightest signs of wear or deterioration, but appeared likely to last for an indefinite length of time. The only parts in which any difficulty had been experienced were the stop gas valves of the stoves; these gave some trouble at first in consequence of a condensation of tar upon them, which prevented them from fitting as tightly as was necessary to avoid leakage, and the tar afterwards ignited and cracked the valve seats; but that difficulty was now entirely got over by not allowing the gas to come into contact with the valve at the time the blast was passing

through the stove, so that any leakage of blast, instead of escaping into the gas, was now discharged into the open air.

Mr. E. A. COWPER remarked that the regenerative hot-blast stoves heating the blast for the Ormesby furnace were the same that he had described at a meeting of the Institution four years previously, (see Proceedings Inst. M. E., 1860, page 54); and the advantages then anticipated from heating the blast in that manner to the high temperature of 1150° Fahr. had been fully realised in actual working. The temperature of 1150° was not attainable with common stoves, in which the heat of the blast seldom exceeded 650° , and could not be increased much beyond that amount on account of the heating being done by means of cast iron pipes. The regenerative stoves however afforded the means of raising the temperature to as much as 1250° or more, the blast being heated by direct contact with the hot mass of firebrick contained in the stove, which had previously been heated by direct contact with flame. The result of employing a blast of that high temperature had been as stated in the paper, that 17 to 18 per cent. of coke was saved in the blast furnace: and there was also an increase of about 20 per cent. in the quantity of iron made, while the quality of the iron was better than previously, more of No. 1 being made.

Mr. F. J. BRAMWELL observed that the arrangement of close-topped blast furnace described in the paper was one of the plans by which the whole of the gas was taken off from the furnace, and there was no combustion of gas out of the mouth of the furnace; and in connection with that arrangement it appeared to be considered that the sole object to be attained was that the materials in the upper part of the furnace should absorb as completely as possible the heat generated lower down. He believed however there was a general opinion that a certain beneficial chemical effect was produced by allowing some of the gas to burn out of the furnace mouth, so that its combustion there might operate in preparing the newly charged materials and rendering them more ready to be acted upon and deoxidised as they descended in the furnace. An open-topped arrangement, similar to that employed

at Messrs. Schneider's furnaces at Ulverstone, had been described at the Liverpool meeting of the Institution last year (see Proceedings Inst. M. E., 1863, page 227), a large portion of the gas being taken off by a vertical tube inserted in the centre of the furnace throat, while the annular space surrounding the tube was left open for the rest of the gas to burn out freely at the mouth of the furnace; and that plan appeared to him to satisfy all the requirements, for while allowing so much of the gas to be taken off as was required for working the blast engine and heating the blast, it still left gas enough burning out of the furnace top to produce the heat necessary for the proper preparation of the materials, and also left the mouth of the furnace open so that the charging was done in the ordinary manner by hand. He thought therefore that an arrangement which allowed of combustion at the furnace mouth and of charging in the ordinary manner fulfilled the required conditions of a blast furnace better than one in which the combustion at the furnace top was entirely stopped by taking off the whole of the gas, and where the charging had to be done by special means in consequence of the top of the furnace being closed.

In reference to the irregular quality of the iron produced where there was any irregularity in the charging of the materials, he thought it most important that great attention should be paid to having the materials all broken to a uniform size for putting into the furnace. For where a chemical process had to be carried on, such as the reduction of the ironstone and other materials of the charge, it was impossible to expect uniformity of results without uniformity of mixture; and if large masses of ironstone and limestone were put into the furnace, they could not be so thoroughly and uniformly acted upon by the heat as if smaller pieces broken to a uniform size were used. A stone-breaking machine for breaking the limestone and iron ore for blast furnaces had been seen in operation by the members at the Liverpool meeting in last year, and had also been described at a subsequent meeting (see Proceedings Inst. M. E., 1864, page 20); which effected the breaking of the materials with great economy, and with a rapidity sufficient for all the purposes of a large ironworks; and he thought such a

machine would be productive of great advantage by conducting to uniformity in the quality of iron made with a given burden.

He had not had an opportunity of seeing the regenerative hot-blast stoves at work for heating the blast, but they were an admirable adaptation of Mr. Siemens' regenerative system: he had seen the regenerative furnaces applied to other purposes where a very high temperature was required, and certainly nothing could exceed the success of their application in such cases. There was no doubt that the mass of firebrick in the regenerative stoves gave the means of heating the blast as high as 1150° Fahr. or upwards, and of maintaining it easily at that temperature, which it would be impossible to accomplish in the ordinary mode of heating the blast through cast iron pipes. Moreover in the regenerative stoves every particle of fuel was utilised, since the heat given out by it was taken up so completely by the firebrick in the regenerators that the chimney flue remained cool enough to allow of the hand being held in it; and the blast being afterwards heated by passing in the reverse direction through the same mass of firebrick, the heat was carried forwards by it into the blast furnace, and great economy was thus effected, the whole of the heat being thereby utilised, instead of a large amount of waste heat escaping to the chimney. There appeared no reason to doubt that the increase in the temperature of the blast from the ordinary heat of 650° to the high temperature of 1150° maintained at Ormesby was attended with the beneficial results that had been mentioned, as regarded economy of fuel in the blast furnace; and that being the case, it might be expected that a still higher temperature of blast would be found productive of yet greater economy. As to what temperature of blast would give the maximum of economical effect, if the question were one of merely melting the ore, no doubt the process of heating the air by means like the regenerative stoves, which utilised nearly the whole of the fuel, might be advantageously carried on until the air was made sufficiently hot to do the whole work of melting the ore without the use of any fuel at all in the furnace; unless indeed before that point were reached the highly heated blast should have an injurious effect on the walls of the

furnace, which however he did not at all fear. But it must be borne in mind that the use of the fuel in the furnace was not merely to generate heat for melting the charge, but that one of its most important functions was to act chemically on the ore so as to fit it for reduction. It seemed to him probable therefore that the limit of useful effect in heating the blast would be reached at that point where its increased temperature would admit of the fuel in the furnace being reduced to the minimum quantity requisite to act chemically on the ore. What that quantity might be was a chemical question: but he had little doubt that the limit was sufficiently far off to allow of the temperature of the blast being still further increased with advantage; and he believed this increased temperature could be obtained by the use of the regenerative stoves, which he was very glad to hear had worked so successfully during the four years they had been in action.

Mr. COCHRANE remarked that, as regarded the burning of the gas in the throat of the blast furnace, he was led to believe that the temperature of the ascending gas on reaching the top of the furnace was not sufficient to produce any chemical effect upon the materials, and the addition of a few feet height at the top of the furnace was only a question of absorbing the heat more completely from the gas before it escaped from the furnace. He had at one time considered that the combustion of the gas in the throat of an open-topped furnace had something to do with dispelling any foreign matter in the coke or the ironstone, or possibly finishing the calcining of any portion of the ironstone that had been imperfectly burned, or drying the materials and warming them more thoroughly previous to their descent in the furnace. But the results of subsequent experience had now led him to conclude that there was not any appreciable difference in yield between a furnace working with a totally closed top and one which allowed the combustion of the gas in the throat. The explanation of this fact appeared to be the same as that which applied to the burning of an ordinary candle, where the gas in the interior of the cone of flame remained so cold that gunpowder might be placed in it without being exploded; and in the same way in an open-topped blast furnace,

the gas by the time it reached the top of the materials was at its lowest temperature, and it had still so much further to ascend before it came in contact with the oxygen of the air necessary to burn it, that the heat generated by its combustion at the furnace mouth, although large in amount, could not radiate back again through the ascending column of gas so as to impart any of its temperature to the materials lying in the throat of the furnace.

As regarded the breaking of the materials previous to charging, there could be no question that if they could be always broken to a uniform size it would be very advantageous to the working of the furnace. This was already accomplished to a considerable extent in the case of the limestone, which was broken by hand labour for the purpose; but in respect to the ironstone, he had no hesitation in saying that any attempt to break it into pieces of uniform size would be frustrated in the Middlesbrough district by the amount of waste made in crushing it, on account of the friable nature of the Cleveland ironstone.

Mr. J. E. SWINDELL mentioned that an attempt had been made eighteen years ago in a blast furnace at Wingerworth in Derbyshire to get the gas ignited and consumed close to the surface of the materials in the furnace throat, in order that the whole of the heat generated by the combustion might be utilised in the furnace. The furnace was about 25 or 30 feet high, with the top entirely closed, the charging of the materials being done through doors provided for the purpose; and a small opening furnished with a damper admitted air to the top of the furnace for the combustion of the gas. The result was that the gas was entirely consumed in the top of the furnace, and the heat produced was so great that the materials at the top were almost in a melting state. The furnace had been worked in that manner for a considerable length of time, but the results were altogether unsuccessful as to quality of iron made and economy of fuel, and the plan was therefore abandoned.

Mr. J. FERNIE had been much struck with the very great waste of heat that must take place at the open-topped furnaces of Gartsherrie and other places in the neighbourhood of Glasgow,

where the quantity of waste gas burning out of the furnace tops appeared largely in excess of what was observed in many English open-topped furnaces; and he could not help thinking the closed top or some other mode of taking off the gas and utilising it might be applied with great advantage to many of the Scotch blast furnaces.

The PRESIDENT enquired whether the iron produced was found to be stronger or better in quality in consequence of the high temperature of the hot blast described in the paper. He remembered that formerly iron used to be produced so strong that the pigs had to be cast with nicks in them for breaking, but latterly the strength had so much deteriorated that a pig would break by merely falling on the ground; and he feared that more attention was now paid to cheapness than to quality of iron.

Mr. COCHRANE said he had not made any experiments to ascertain the actual increase of strength in the iron produced with the very hot blast employed at Ormesby, but he could state positively that there was an increase of strength, as shown by the fact that the work of breaking the pigs after each cast was now much heavier, which was a rough test of the increased strength. There was a decided improvement in the purity of the iron made with the hotter blast, which would no doubt explain its increased strength. In the Middlesbrough district it was found that a little scum of impurities rose to the surface of the melted iron in the blast furnace, which was sometimes very objectionable in casting; but with the hotter blast there was less of this scum rising, showing that there was increased purity of the iron produced. In fact as the greater part of the impurities in the iron arose from the coke, the smaller quantity of coke used with the hotter blast gave less opportunity for these impurities to pass into the iron.

Mr. J. ANDERSON thought it strange that makers of iron on a large scale should allow the question of quality to occupy so little of their attention. The fact that the tensile strength of different descriptions of iron in the pig ranged from as low as only 4 tons per square inch up to 15 tons, with all the strengths between, showed that there was something to be done by the iron maker, and that

the founder had very little to depend upon previous to trial as to the kind of iron that should be used for any purpose, since with the inferior irons the strains to which they would be subjected in use must often approach very nearly to their breaking strength. He thought the iron maker should ascertain the exact quality of the iron which he made, so as to be able to state definitely how good it was in respect to toughness, elasticity, and ultimate tensile strength. If these points were more attended to, instead of merely the production of iron in great quantities, it would in the long run be the better for the country at large.

Mr. W. HADEN remarked that if a superior quality of iron were desired it could always be obtained if a proportionate price were paid for it. But there were many other requirements also for which a very inferior quality of iron was quite suitable; and if these were to be overlooked, a large amount of the material in the various iron making districts would lie worthless. The great object to be aimed at in every district was to utilise the material of that district to the utmost extent.

Mr. J. ANDERSON thought that, if there were greater facilities for getting good iron, a proportionate diminution might be made in the dimensions of castings, compared with those made of the inferior iron at present employed; and if more care were bestowed upon getting the greatest strength from the ironstone of a district, and the chemical constituents of the iron were attended to, the minimum tensile strength of the iron in the pig might probably be brought up to 8 tons per square inch or upwards. Thus only half the weight of iron would have to be used in those structures for which the inferior iron was at present employed.

Mr. J. E. SWINDELL thought the only excuse for not using the better qualities of iron was their high prices; but the tensile strength of 8 tons per square inch that had been mentioned appeared to him to be considerably below the actual strength that was generally obtained from the best makes of pig iron. At his own works in the South Staffordshire district the tensile strength of bars 1 inch square of cold-blast iron cast direct from the blast furnace was found to be 14 tons in the regular make, though it

was not possible for that strength to be guaranteed in all castings made from such pigs, because the metal might be so treated subsequently in the foundry as to have much of its strength destroyed. The mechanical qualities of any sort of iron, its strength, toughness, and elasticity, were the principal points to be regarded, he considered; and the question of chemical composition and the minute proportions of foreign ingredients mixed with the iron appeared to him of very secondary importance.

Mr. F. J. BRAMWELL concurred in thinking that the chemical composition of iron should be viewed as of secondary importance in comparison with its mechanical qualities. If a number of inferior descriptions of iron were found by chemical analysis to contain a certain foreign ingredient which was found to be absent from other irons of a better class, that afforded a presumption that the particular ingredient in question deteriorated the quality of any iron containing it: but the exceptions to this inference were found to be so numerous in practice that it would be a mistake to reject any iron merely on the ground of its containing some special ingredient, while its mechanical properties might notwithstanding be such as to place it among the class of good irons. He therefore considered the mechanical qualities were in every case those which should be first regarded. In describing the strength of any make of iron, one thing to be stated was the condition that the iron was in, whether in the pig or after a subsequent process of casting, as the strength was much affected by difference of the conditions in that respect. In the case of some iron from Nova Scotia which he had had occasion to test, he had found that in the pig it bore a tensile strain of only $7\frac{1}{2}$ tons per square inch; but after repeated fusion and mixing with its own scrap, the same iron bore an average tensile strain of $18\frac{1}{2}$ tons per square inch, while the highest strength obtained by that means was as much as $19\frac{5}{8}$ tons per square inch, as proved by the testing machine at Woolwich, showing how greatly the original strength in the pig might be increased by subsequent treatment.

Mr. J. ANDERSON remarked that having lately given a good deal of attention to the properties of iron in its different characters

of wrought iron, cast steel, and cast iron, he had come to the conclusion that the chemical composition of the metal was the great question. He had found that wrought iron which was most nearly pure, containing the least amount of carbon, had a tensile strength of about 20 tons per square inch, and in the irons of Scotland and the steely irons of Yorkshire the strength varied from that amount up to 28 tons per square inch, while cast steel containing $1\frac{1}{2}$ per cent. of carbon had an ultimate tenacity as high as 75 tons; whereas in cast iron, containing the largest proportion of carbon, the strength declined to 8 tons and downwards as low as 4 tons per square inch. All these descriptions of iron, excepting the purest with the tensile strength of about 20 tons, had their strength increased by plunging them while in a heated state into cold water. He had also found that the facility of welding any description of iron was in proportion to its freedom from the chemical constituent, carbon, which increased its tenacity; so that the purer and weaker irons welded more readily than those containing more carbon and possessing greater tensile strength. Thus the steely irons of Yorkshire became very difficult to weld in the stronger qualities, and the next gradation in the scale was the mild steels which he was now using for guns. These had very nearly the same constituents as the Yorkshire iron, and were affected to nearly the same extent by being made red-hot and plunged into water. The various mechanical properties of the different descriptions of iron were now becoming generally understood, but the great question that still remained for solution was altogether a chemical one: namely, what it was that produced such great changes of quality in the different sorts of iron, and particularly what it was that caused iron to become so much stronger when heated red-hot and plunged into water.

Mr. P. D. BENNETT thought the subject of the different qualities of various descriptions of iron was of the greatest importance to the makers of iron, and he would be very glad if an explanation could be given as to why there was so much difficulty in getting Staffordshire iron to stand tests which were borne by Scotch iron of much less cost. His own practice in testing iron was to have a

test bar cast 2 inches deep by 1 inch wide with 3 feet between the bearings, which ought to carry a load of 28 cwts. in the centre before breaking, if the iron were of at all a good quality. But in the case of the Staffordshire district he had found it difficult to get any of the cheaper iron to stand that test, while Scotch iron would readily stand 32 cwts.; and to get Staffordshire iron to stand the same test as the Scotch, the price would be as much as 20s. to 30s. per ton higher than the Scotch. In some recent experiments with the best cold-blast Staffordshire iron he had succeeded after much difficulty in getting a test bar to stand a weight of 37 cwts., which was the highest test he had been able to attain with it; but the price in that case was as much as £5 10s. per ton as compared with only £3 10s. for Scotch iron of the same strength. He hoped therefore that the reason of this great difference would be more satisfactorily explained than had yet been done.

Mr. E. A. COWPER thought there was still much to be done in respect to the chemical investigation of the different qualities of iron, in order to ascertain clearly what was the cause of the differences that were met with; for when this was known, so that the quality of any desired sort of iron could be fully described, he had no doubt the iron makers would find the means of producing that quality of iron readily enough. At present chemistry had not gone far enough in this subject; for in a recent case one of the strongest irons known had been rejected on chemical reasons alone.

In reference to increasing the strength of iron by heating it red-hot and plunging it into cold water, it was found very advantageous, in the case of casting chilled rolls, to melt and cast the iron into cold water two or three times beforehand. He did not know what change this made in the nature of the metal, but it had the effect of causing the iron to chill more completely in the final casting, and thus increased the hardness and durability of rolls cast in that way.

Mr. J. ANDERSON observed that a great deal had already been accomplished and was still in process of being done by government towards ascertaining the chemical qualities of iron, and to a certain extent these endeavours had been successful; but because chemical

investigation had not always led to correct results at present, it ought not on that account to be disparaged.

Mr. F. J. BRAMWELL thought the value of chemistry in connection with the properties of iron should not be depreciated ; but on the other hand, when the sole object was to get iron that should satisfy certain mechanical requirements, if the chemical test and the mechanical test were at variance, it was a mistake to accept the chemical test in lieu of the mechanical. In any case of a discrepancy between the two, the test which was practical should be adopted, and not that which was only a means of arriving at the practical by another road.

The PRESIDENT considered the experiments and researches that had been referred to as being made by the government must tend to a good result ultimately, and were leading the way for further investigations by individual makers and consumers of iron, who were all anxious to get better iron. A very elaborate machine was now in course of construction by Mr. Kirkaldy, for the purpose of testing iron in respect to all its various mechanical properties, which would enable the makers of iron to ascertain with great accuracy the quality of the metal which they produced.

He proposed a vote of thanks to Mr. Cochrane for his paper, which was passed.

The Meeting was then adjourned to the following day. In the afternoon the Members were conveyed by special train, granted for the occasion by the Edinburgh and Glasgow Railway Company, to visit the Mugdock Reservoir of the Loch Katrine Water Works, with the Straining Well, the Outlet of the Loch Katrine Aqueduct, and the Delivery Sluices for the supply of Glasgow. The Members were received at the Milngavie Station and accompanied over the works at Mugdock by the Lord Provost of Glasgow and the authorities of the Water Works ; and returned to Glasgow in the evening by special train.

The Adjourned Meeting of the Members was held in the Institution Rooms, St. George's Place, Glasgow, on Wednesday, 3rd August, 1864; ROBERT NAPIER, Esq., President, in the Chair.

The following paper was read :—

ON IMPROVEMENTS IN HEAVY TOOLS
FOR GENERAL ENGINEERING
AND IRON SHIPBUILDING WORK.

BY MR. JAMES FLETCHER, OF MANCHESTER.

During the last thirty years the great rise and progress have taken place in the construction and application of general Engineering and Iron Shipbuilding Tools, their manufacture now forming a very important branch of mechanical engineering. Forty-five years ago, at the commencement of the writer's career as a mechanic, tools were of a very rude and primitive description, the lathe and drill being about the only ones then in general use; slide lathes were possessed only by a few persons, being made with great labour and expense, and very inferior in point of workmanship.

The introduction of the planing machine however and its subsequent development effected an entire change in the manufacture of tools and machinery of every class, giving the means of carrying out with facility many works which had been left unattempted previously as too expensive or impracticable, and opening the way for improvements and invention generally; and in a short time these machines became indispensable in every workshop. The slide lathe became then comparatively easy of manufacture, and in conjunction with the planing machine and self-acting drill formed a most important feature in the advancement of engineering work. Still much remained to be effected: a large proportion of work was done by hand, especially the smaller portions of machinery, until slotting and shaping machines were brought into use, and special tools adapted for all parts where a quantity of work was required to be produced. By the gradual introduction and perfecting of the regulator screw, the wheel cutting engine, standard gauges, large surface plates, long straight edges, and scraped surfaces,

combined with the improved tools, not only was the amount of manual labour considerably diminished, but the work was done more expeditiously, and a much greater degree of accuracy was attained, whereby the workmanship in all classes of machinery was remarkably improved and at a great reduction in cost. As engineering skill was brought to bear on schemes which could not previously have been carried out, so were tools enlarged and new ones invented, to meet the exigencies of new works; until engineers and others became really dependent for the accuracy and execution of their work upon the tools that could be employed for the purpose. The steam engine, with all the inventive genius that has been concentrated upon it, would without these tools have still been most imperfect in construction, and would have formed a wide contrast to the engines erected at the present day, in point of excellence of workmanship, durability, and cost. Many instances could be given where tools of unusually large dimensions or the most minute description are indispensable for the execution of the work required.

The great change which has taken place in the substitution of wrought iron for wood or cast iron, especially in ship and bridge building, is a subject worthy of special attention. In ship building the use of wrought iron has advanced with such rapid strides during the last twenty years as to cause a complete revolution in the trade. The transition was so sudden and the demand so great that much difficulty was experienced in procuring a sufficient number of the necessary class of workmen, until those who had previously been employed as shipwrights in building wooden vessels were in a short time enabled, by the assistance of improved tools and appliances, to compete with more practised hands, and to cope easily with the heavy modern work. Improvements in the construction of iron ships were then rapidly developed. New tools were called for and produced, by means of which the work has been materially improved and facilitated; the edges of the plates are now planed to make perfectly fitting joints, and multiple drilling machines are rapidly coming into use for drilling a large number of holes at once in the plates or keel bars.

Another important feature in connection with improved tools is the direct application of steam power to individual machines, especially those for the purpose of punching and shearing plates or cutting bars, &c., by the combination of a small steam engine with each machine; thus rendering the machines portable, entirely self-contained, and independent of other sources of driving power, and thereby saving in many instances the necessity of running a large engine and quantity of shafting to drive only one or two machines, when pressed for the work upon which they are engaged, and entirely dispensing with shafting and the usual attendant expenses. By this means and by the use of an underground steam pipe with branches at convenient points, either in workshops or along the sides of docks, these machines may be moved about to any part required, and thus obviate the inconvenience and loss of time in carrying work to and from the machines. Steam pipes of great length are now being used and are found very satisfactory for purposes of this description; and this plan makes a much more convenient and less costly arrangement than shafting, which requires constant attention.

In the earlier construction of the Lathe the slide rest was the first great step towards the principle of the slide lathe, and no doubt led to that invention, which was considered impracticable before planing machines were made of sufficient magnitude to plane a lathe bed of even small dimensions. A few slide lathes had indeed been made, the beds of which were composed of a timber framing, covered with iron plates on the upper side to preserve the surface, similar to those which were previously used for the ordinary hand lathes, with the exception that the outer edges of the iron plates were made of suitable shape to form the Vs for the carriage to slide upon. It was not however until some time after the introduction of the planing machine that, the cost of workmanship being considerably lessened, slide lathes came into general use and their utility was fully acknowledged and attention directed to their improvement.

The application of a screw to the slide lathe, so as to render it capable of both sliding and screw-cutting, was the next important

improvement; and a great amount of time, perseverance, and capital was expended by a few persons in endeavouring to perfect this portion of the lathe. A short screw was first made as accurately as possible, with the rude means then possessed, from which one was cut double the length, by changing the turned bar end for end in the lathe after cutting one half. Subsequently by following out this principle screws were capable of being made of any length required.

After this the surfacing motion was introduced; and also the use of a shaft at the back of the lathe, in addition to the regulator screw, for driving the sliding motion by rack and pinion, instead of both the motions of sliding and screw-cutting being worked by the screw alone. For it was found that the threads of that portion of the screw nearest the fast headstock, being most in use, were worn thinner than the other parts; and in consequence the lathe did not cut a long screw with the degree of accuracy which it otherwise would have done.

Thus step by step improvements were gradually brought forward; the four-jaw and universal chucks and other important appliances were added, so as to render the lathe applicable to a great variety of work, even cutting spiral grooves in shafts, scrolls in a face plate, skew wheels, and also turning articles of oval, spherical, or other forms. The duplex lathe, with one tool acting in front and the other behind the work, is also found to be a very useful arrangement for sliding long shafts, cast iron rollers, cylinders, and a great variety of work, where a quantity of the same kind and dimensions has to be turned.

The lathe shown in Fig. 1, Plate 59, is an improved lathe designed for the purpose of turning long shafts, screws, or other articles. The bed A is 40 feet long, cast in one piece and planed the entire length at once. It is provided with two pairs of headstocks, placed right and left hand, each pair having its own carriage and tool rest, and working entirely independent of the other; the one pair BB being 15 inches high to the centre, and the other CC 12 inches high. In connection with the larger headstocks BB is a regulator screw running through the entire length

of the bed, by means of which, when the other headstocks CC are removed, a screw $35\frac{1}{2}$ feet long may be cut at once. The smaller headstocks CC, by means of a separate shaft at the back of the lathe, are capable of sliding an article 25 feet long, and can also if required be provided with a screw-cutting arrangement. Thus this lathe possesses the advantages of being used as two lathes for work of an ordinary character, but at the same time a very long shaft may be turned when required. In many workshops a long lathe is an absolute necessity, although the whole length of the bed may not be required many times during the year; and unless some similar arrangement to the one above described is adopted, a large portion of the lathe bed, taking up valuable space, would remain idle and useless the greater portion of the time. Again in sliding long shafts the two carriages and tools may be in operation at once upon the same piece of work, and thus economise time. The headstocks being placed right and left hand, the loose headstocks are thus able to accommodate each other to the different lengths of work, thereby avoiding the necessity of moving the fast headstock and top cone pulley when any work above half the total length of bed is to be turned.

Figs. 2, 3, and 4, Plates 59 and 60, represent a slide lathe for turning large marine-engine crank-shafts or other articles up to 40 tons weight, or screw propellers up to 20 feet diameter. The headstocks BC are 4 feet 6 inches high from the face of the bed, which is 40 feet long. The main driving spindle D is of cast iron, 18 inches diameter in the front bearing and 12 inches in the back bearing, arranged as an ordinary treble-gear lathe which can be worked single, double, or treble power. The cone pulley E, the largest speed of which is 3 feet 6 inches diameter by 6 inches wide, runs loose upon the spindle D. The faceplate F is 12 feet diameter and has on the back a large internal toothed wheel G, Fig. 3. By means of two pairs of driving pulleys on the countershaft, the lathe may be worked at thirty different speeds, to suit the diameter of articles to be turned. The fast headstock casting B is in one piece, and without spindle or appurtenances weighs $11\frac{1}{4}$ tons. It is tied to the bed A by the tie plates H, Fig. 2. The bed is 10 feet

wide over all, and is composed of two lathe beds AA, Fig. 4, each cast in one piece 40 feet long, and held firmly in a parallel position by distance feet or foundation plates K, having strips and bolts to bind the beds in their places. When it is required to move the bed endways to accommodate any large article on the faceplate, the strips in the distance feet K are slackened so as to allow the two long beds AA to slide through them, the motion being given at the end by means of worm wheels and screws L, Fig. 2. The end foot or distance piece K nearest the fast headstock B is fixed to the long beds AA and travels with them upon the tie plates H, so as to support their ends whilst turning articles on the faceplate F. Two self-acting sliding carriages M and N are employed, Fig. 2, upon one of which M, Fig. 4, is a slide rest of ordinary construction and great strength; the other carriage N has a rest made very narrow, with a wrought iron tool slide, and is for the purpose of turning out crank sweeps. The self-acting motion is driven by a strap from the spindle D to a pulley O at the back of the lathe, Fig. 3, and is provided with a reversing apparatus to enable the carriages to slide in both directions. This motion can be thrown out of gear independently in either of the carriages M and N, which are provided with an arrangement for moving them on the bed by hand. An eye bolt is screwed in the front part of the loose headstock C, and a corresponding one upon the nearest carriage N, so that the two can be coupled by a short chain or shackle, and the loose headstock C can thus be drawn upon the surface of the bed A to any required position by the hand motion of the carriage N. The total weight of this lathe, which is now in course of construction for the Lancefield Forge in Glasgow, will be upwards of 70 tons.

The Planing Machine is one of the most important tools in use, and has done more towards the advancement and success of engineering work than any other invention, with the exception of the lathe; and has passed through a great number of changes since its first introduction down to the present time.

In the first planing machines the table was moved by means of a chain winding on a drum, as in the old hand machines.

But this mode was found to be very objectionable: the cut was unsteady, and when the tool was suddenly relieved at the end of its cut, the table had a tendency to spring forwards; it was also driven at the same speed both forwards and backwards, and thus a great loss of time was occasioned. This was much improved upon by the use of a rack and pinion, arranged to give a quick return motion, and also afterwards by the screw arrangement. Much difference of opinion has existed as to the relative value of the rack and the screw for driving the table of planing machines. The writer will not therefore go into this question further than to state that his own long experience in this class of machines, after having made a large number with both appliances, has led him to the opinion that the rack is decidedly the most preferable mode of driving.

In some of the earliest planing machines the Vs were made inverted, evidently with the idea of preventing any cuttings that fell upon the wearing surfaces from remaining upon them. They proved however to possess no advantage even in this particular, as the finer portions of the cuttings still adhered; and in addition it was found that from the motion of the table the oil by its own gravity would not remain upon the surfaces, and thus caused them to cut and wear away quickly. They were afterwards made an ordinary V shape and found to answer much better, as the V formed a reservoir to contain the oil in a groove at the bottom, from which it was raised at each stroke by the motion of the table and the apparatus attached for that purpose. The Vs have been constructed of different angles and widths of surface; but it is the writer's opinion that at the present time many machines are made with the angle too obtuse, and the surfaces widened to too great an extent. In machines with very shallow Vs, taking a heavy cut off a light article with the tools on the uprights, the table is liable to shift sideways, causing the tools to dig into the work and occasion much mischief. Also with very wide Vs the table when making short strokes cannot work the oil up to the top of their surfaces, and thus allows them to cut or gall. The writer has in use a planing machine with a bed 54 feet long, the Vs of which, shown one quarter full size in Fig. 5, Plate 61, have only 2 inches of surface on

each side, and are planed to an angle of 85 degrees. This machine has been working upwards of twenty years, and for the last six years both night and day; it has been employed during the whole of that time upon very heavy work, ranging from 5 to 20 tons. The **V**s are still in good condition, apparently very little worn, and the work the machine does is at the present time perfectly true. The bed is in three parts jointed and bolted together, and the table in two parts; since at the time it was made there was no machine capable of planing a very long piece, and this was considered to be one of the largest then in existence. The writer has also a planing machine made about the same period with a **V** on one side of the bed and a flat surface on the other, which plan he found was very objectionable, on account of the two surfaces not wearing equally and the oil working off the flat surface.

The planing machines were further improved by the use of two toolboxes on the cross slide, and by the application of slide rests or toolboxes fixed upon the uprights, self-acting vertically, for planing articles at right angles to the tools on the cross slide. The reversing toolbox is a very ingenious and useful contrivance for planing flat surfaces; but that plan is not so well adapted for general purposes. Planing machines have like other tools been specially adapted to a great variety of work, and the writer has made them with different numbers of tools up to as many as sixteen, all of which were in operation at once.

The great changes which have lately taken place in the manufacture of wrought iron and steel ordnance, and the revolution they have caused in the construction of vessels of war, have called into requisition a great many alterations and adaptations of the present machines, as well as many entirely new ones. The planing machine especially has been called upon to do work of a very curious and intricate character, namely that of planing the edges of armour plates to different curves, shapes, or angles. In most cases this has been accomplished by a pattern bar of iron or steel, placed on edge in a small chuck fixed upon the surface of the table, adjustable by set screws, and shaped to the form to which it is required to plane the edge of the plate; as the table travels, this

bar, which runs between two circular rollers attached to the underside of the tool slide, moves the tool sideways according to the amount of curve in the shaper or guide bar, the toolbox being disconnected for this purpose from the screw in the cross slide.

Figs. 6 to 9, Plates 61 and 62, represent one of the Duplex Planing Machines made by the writer. This machine is arranged with double beds A A and double tables B B, Fig. 8, each table having a separate set of gearing, with starting, stopping, and feed motions. There are two toolboxes C C on the cross slide D, each of which is independently self-acting, so as to work with its own table. Thus the two tables may be used separately as two smaller machines working independently of each other and capable of planing different lengths of work at the same time; or when planing a large article the two tables, gearing, and motions may be coupled, so as to form one large machine: an arrangement rendering the machine capable of doing a great variety of work. Also one table may be fixed stationary as a bed-plate, to bolt awkwardly shaped or long pieces of work upon, whilst they are planed by a slide rest fixed upon the other table. When used as one machine, both sets of straps and gearing are in operation, and are reversed by the stops of one table only, so as to ensure the straps moving at the same time.

The machine shown in Figs. 6 and 8, Plates 61 and 62, is capable of planing articles 10 feet wide and 10 feet high. The racks on the underside of the tables B B are 3 inches pitch, with stepped teeth, as shown enlarged in the plan, Fig. 7; the wheel E working into the rack is 3 feet 9 inches diameter at the pitch line, and is driven by a smaller pinion F, Fig. 6; the large wheel E being only for the purpose of transmitting the power from the pinion F to the rack. By this arrangement the large wheel E has a better hold upon the rack, and a steadier motion is obtained; and also the pulleys and driving gear G can be placed entirely behind the face of the uprights H, so as to leave the front of the machine perfectly clear, that the straps may not be in the way when taking the work off and on. The pulleys G being below the ground

line may be driven by a horizontal underground shaft at the back of the machine, and no straps will then be visible. The writer has made machines of this description with beds 40 feet long to plane work up to 14 feet in width, the beds of which were constructed the same as shown in Fig. 9, being made in two halves A A, which are jointed longitudinally with a projection I on one half fitting into a corresponding recess in the other, and securely fastened by bolts at intervals throughout the entire length.

This machine is particularly well adapted for planing armour plates. Two plates can be planed at once on each table, one being placed upright and the other horizontal, so as to be operated upon by the tools on the cross slide and the upright at the same time; or whilst two plates are being planed on one table, the workman may be fixing two more on the other, and thus keep the machine constantly employed. One workman is sufficient to attend to both sides of the machine, thereby saving labour. By having a stationary table fixed at one side of the bed, upon which the four ends of four other armour plates are bolted, and adding an angle bracket and slide rest upon one of the moving tables, the four ends are planed at the same time.

The Slotting Machine, of which the engineers in Glasgow can justly boast the heaviest examples, was originally introduced for cutting small wheels, levers, &c., mostly for self-acting mule and loom work; and was afterwards adapted to a great variety of work by the application of a circular table, which was an improvement of the greatest importance, especially in large machines for slotting or shaping large cranks or other similar work; this is now done to such perfection as to require merely drawfiling and polishing to give the work a perfect finish. Many kinds of quick return motions have been employed for the purpose of saving time in the return stroke of the tool, and to give it a regular and steady movement in the cutting direction. Of these the principal are the eccentric wheels, the eccentric motion, and lastly the lever motion, which makes an excellent and steady movement and is now very much applied to shaping machines.

One of the large slotting machines made by the writer has a stroke of 3 feet, and the framing is capable of taking in an article 12 feet diameter; it has compound slides and a self-acting circular table 6 feet diameter. The ram moves in a vertical slide, which can be raised or lowered to suit the depth of work on the table, so as to form a support to the ram when taking a heavy cut. The motion applied to the tool slide is the lever and connecting rod, arranged so as to gain power and give an almost uniform motion in the cutting direction and an accelerated speed in the return stroke.

A difference of opinion exists as to the best form for constructing slotting machines, whether with the double standard, or the projecting single frame. For machines required to take in a very large diameter, the writer would give the former plan the preference.

Figs. 10 to 14, Plates 63 and 64, show a Double Lever Punching, Shearing, and Angle Iron Cutting Machine. The strong hollow cast iron frame AA is planed at each end for the reception of the punching slide B and the shearing slide C. The machine is put in motion by a steam engine D, Fig. 11, fixed upon the outside of the framing, and connected to a crank pin in the flywheel E, driving by the pinion F on the first motion shaft into the large wheel G, Fig. 12, which has cams H cast on each side in opposite positions, so as to actuate the levers KK alternately. These cams are provided with circular rollers, which run against the underside of the levers K during the operation of punching or shearing, and thus prevent any scraping or friction of the surfaces in contact. The levers K are of wrought iron, steeled where operated upon by the cams and where they work in the slides B and C, having the pins I for their fulcrums. The punching slide B, shown enlarged in Fig. 14, is provided with a block J, which can be drawn out from under the end of the lever to throw the punch slide out of gear. At the shearing end C, shown enlarged in Fig. 13, an adjustable stop L is added immediately in front of the shears, for holding down the plate whilst shearing, and thus causing it to be cut square on the edge: this takes the strain of holding down the plate from

the workman, and prevents short pieces of metal from getting down between the cutters and breaking the machine.

Upon the end of the centre shaft is forged an eccentric M, Fig. 10, working into a block in the ram N, the lower end of which is provided with suitably shaped cutters for shearing bars of angle iron O. This slide is placed at an angle of 45 degrees, and has also a disengaging motion, so as to be thrown out of gear whilst a long bar of angle iron is being put between the cutters and set to the proper place or marks for being cut off correctly. This slide may also if required be placed in a vertical position for cutting straight bars. In cutting long bars of bent angle iron however, with the slide N placed in a vertical position, one portion of the bar would project either upwards or downwards at an angle from the ground, and would consequently be very awkward for the workman to hold; but by placing the slide at an angle, as shown in Fig. 10, the bars are kept in a horizontal line parallel with the ground whilst being cut.

This machine possesses all the advantages of the old lever machine and the eccentric machine combined; the former of which has long been acknowledged to be the most simple and useful. The cams H, Fig. 12, are constructed of such a shape that the operation of punching or shearing is completed and the slide returned to the top in half a revolution of the machine, the whole slide remaining stationary during the other half revolution whilst the workman is adjusting the plate for the next stroke. This enables the machine to be worked one third quicker than eccentric machines, and still leaves the workman as much time to move the plate; since in eccentric machines the punch or shears is always being either raised or lowered, instead of being stationary during part of each revolution. The levers KK are left sufficiently long and heavy at the tail end to overcome the weight of the slides B and C and the friction of the punch or shears upon the work. Many of the old machines were made without rollers either in the lever end or in the cam; and in consequence of the wear which took place, the stroke of the punch or shears was gradually lessened until the worn out parts had to be renewed. By the application of rollers however

in the cams H, these objections are entirely obviated; and instead of scraping the oil from the wearing surfaces, the roller tends to keep it on.

For the purpose of obtaining greater accuracy in dividing out the holes in bridge plates, boiler or ship plates, a dividing table has been used, and machines have been arranged to punch several holes at once. This was certainly a great improvement upon the old method, since in addition to the accuracy attained very much more work was accomplished in the same amount of time. Still the work was not of a satisfactory description: in punching the holes the iron is disturbed or fractured for some little distance round the hole, thus weakening the plate; and in consequence of the taper which there must necessarily be in all punched holes, the rivets do not thoroughly fill up the space, especially when more than two plates are joined together.

The faults of punched work above mentioned were so apparent when wrought iron bridge building became general, that they led to the introduction by Messrs. Cochrane of the Multiple Drilling Machine, described at a former meeting of the Institution (see Proceedings Inst. M.E., 1860, page 201), for drilling a large number of holes at once in bridge plates.

It has been found desirable to make this principle of drilling machine more universal in its application, and a machine for this purpose is shown in Figs. 15 and 16, Plates 65 and 66. The strong base plate AA extends the entire length of the machine, about 18 feet, with three circular openings along the centre line, large enough to admit the hydraulic cylinders CC, by which the table BB carrying the plate to be drilled is raised and pressed against the drills with the necessary force. The end frames DD are bolted to the base plate, and upon them are fixed guides adjusted to each corner of the table; they also support the girder EE, which carries the drill frames. The ends of the girder are fitted in planed grooves, and it is made in halves, which can be set wider apart without altering the gearing, by inserting cast iron packings of the requisite thickness and longer bolts at the joint F,

Fig. 16. The two halves of the girder can also be turned with the drill frames inwards if required, and adjusted to a distance of 4 inches apart for the two rows of holes and upwards.

Each drill is held in a separate frame G, as shown enlarged in Figs. 17 to 20, Plate 67. These frames are all bolted on the girder E at the proper distance apart by means of bolts, the heads of which are in T grooves cast and planed in the girder, Figs. 18 and 19. Two small projections on the drill frame G are planed to fit the recesses of these grooves, as seen in Fig. 18, and the drill frames G are thereby all held at exactly the same height and are easily moved longitudinally to any position along the girder E. Each drill spindle is fitted with an adjustable tail pin and lock nut H, which receives the upward pressure of the spindle; and a conical bearing is provided at the lower end of each frame G, which prevents the drill spindles from wearing out of truth. The drills are all turned parallel for a short distance at the upper end, as shown enlarged in Figs. 21 and 22, and fit in parallel sockets, which admit of short drills being adjusted to the same length as longer ones, by putting some small burrs or punchings from the punching machine of the required thickness into the drill sockets above the drills; and the drills are fastened in the sockets by a set screw.

Each drill spindle is driven at the top by a pair of spur mitre wheels II, which may be described as each consisting of a short section of a $3\frac{3}{4}$ inch diameter twelve-threaded screw, of which the threads are about 12 inches pitch; that is to say each thread or tooth if continued would make one complete turn round its shaft in 12 inches length. A long steel shaft J, $2\frac{1}{4}$ inches diameter, with a groove throughout its length, passes through each drill frame G and its vertical spur mitre wheel I, giving motion to each drill spindle. This shaft is driven by a pair of strong bevil wheels K, Fig. 16, in the proportion of $1\frac{1}{2}$ to 1, the larger one being on the shaft J; and the wheels K take their motion direct from the pulley shaft L, which is driven with pulleys 3 feet diameter and 6 inches wide, and runs at about 90 revolutions per minute, giving about 60 revolutions per minute for the drills.

The application of the spur mitre wheels II, Figs. 17 to 20, in this machine, for driving the drill spindles, enables the spindles to be arranged in such a manner that they are capable of being moved to suit different pitches of holes. In consequence however of the wheels II being $3\frac{3}{4}$ inches diameter, holes could not be drilled at a less pitch than that dimension with a single driving shaft J; but another application of the same mode of driving is shown in Figs. 17 to 20, by means of which the drill spindles can be got to within $2\frac{1}{2}$ inches from centre to centre, with the same diameter of driving wheels I: this is effected by using two long steel driving shafts JJ, instead of a single one as previously described, each shaft driving every alternate drill spindle.

The hydraulic cylinders CC, Figs. 15 and 16, are similar to those of hydraulic presses, and are used to raise the table with the work on it up to the drills, instead of gearing which would necessarily be much slower. A pair of strong $1\frac{1}{4}$ inch diameter pumps, worked by eccentrics on a shaft, force water into an accumulator, which consists of an upright cylinder fitted with a piston properly weighted; and there is a self-acting apparatus which throws the pumps out of gear when the accumulator is full. The hydraulic cylinders are connected with the accumulator by a two-way cock; and on turning the water on, the table B immediately rises. When the pressure is to be removed, turning the cock back stops the pressure from the accumulator, and at the same time allows the water to escape from the cylinders, causing the table to fall immediately. The working pressure of water is about 3 cwts. per square inch, which produces a pressure of about 6 cwts. per drill. A plate is drilled in 12 to 15 minutes. A strong parallel motion gear M is fixed under the drill table B to prevent it from lifting at one end when only the drills at the other end are being used, or when only one row is in use.

These drilling machines are now being used by Messrs. Kennard for drilling the plates and bars required in the main girders of the new bridge to be placed over the Thames at Blackfriars. The truth of the drilled holes is so complete that when a number of plates with holes drilled for 1 inch pins are put together indiscriminately,

and four turned pins passed through the corner holes, the holes fit so accurately throughout the entire lot of plates that a pin 1 inch diameter can be driven through the lot at any hole with a light hand hammer. In consequence of this superiority of the work, a great diminution in the cost of labour takes place in putting the parts together, saving the drifting of the holes and the strain put upon the plate which necessarily takes place when rivetting punched holes. In addition to this the fibre of the iron retains all its strength and tenacity, and there can be no doubt that the extra work of manufacture is fully compensated for by the greater strength of construction, and the decrease of cost in putting the plates together.

Several other useful machines are constructed for bridge and ship building purposes, amongst which may be named:—a machine for shearing plates up to 1 inch thick with revolving circular shears; machines for planing plates with a travelling tool, and also with a revolving circular disc containing a number of tools; and machines for bending garboard strakes, angle iron, and deck beams for ships.

A Nut Making Machine is shown in vertical section in Figs. 23 to 25, Plates 68 and 69; the principal features of which are the manufacture of nuts from a heated bar of iron at a single operation, by cutting off from the bar a piece to form the blank, which is swaged into shape and the hole punched through it while still hot. The blank is powerfully compressed between the pair of swages, while in the diebox, before the hole is punched, in order to make the nut solid and to shape it with smoothness and precision; and the hole is then punched while the nut is still confined in the diebox and under the heavy pressure of the swages, so that it is prevented from bursting or straining during the operation of punching. Figs. 24 and 25, Plate 69, illustrate the working of the machine, in which the end of the heated bar A being pushed up to the stop B is cut off by the descent of the diebox C on to the stationary die J; and the blank cut off being enclosed in the diebox C is then subjected to severe compression by the descent of the upper

swage I, which works within the diebox C and fills it closely. The blank is then punched by the descent of the punch D, whilst still under compression in the diebox C; and the finished nut is liberated by the rising of the diebox C and punch D, whilst the upper swage I remains stationary and pushes the nut out below.

The diebox C, Figs. 24 and 25, is carried on the crosshead E, and consists of a cast iron block, into which is fitted the steel die having a hole to correspond with the shape of nut required to be made. The die is held down in the diebox by a circular wrought iron plate or washer let into the recess in the top of the block. The upper swage I is made of steel, and corresponds in size and shape with the diebox in which it is to work; the upper end is enlarged, to prevent it from dropping out when the diebox rises. The hole drilled through the centre of the upper swage I, for the punch D to work through, is made larger at the upper end, and small enough at the lower end for about half an inch of its length to fit the bottom end of the punch D, which makes the hole in the nut. The bottom face of this swage I is slightly recessed, in order to form the impression of a washer upon the upper face of the nut. The lower swage or stationary die J is made of steel, and has also a hole through its centre for the reception of the burr punched out by the punch D.

The end of the heated bar A, Fig. 24, is laid upon the rest F, which is fixed upon the crosshead E that carries the diebox; and as soon as the knocker G, Fig. 23, has passed from between the upper and lower swages, the bar is pushed forwards up against the stop B, as shown in Fig. 24. The cam H, Fig. 23, upon the main driving shaft O of the machine, then depresses the crosshead E by means of the lever K; and the blank to form the nut is thus sheared off from the end of the bar A by the diebox C, and enclosed within the diebox, as seen in Fig. 25. For although the diebox C, at the moment of beginning to descend, is filled by the swage I, there is nothing to cause the descent of this swage until after the blank has been sheared off and enclosed in the diebox; then the crosshead E comes in contact with the check piece L, which presses upon the top of the swage I, and the further descent of the crosshead through

the last portion of its stroke thereby compresses the blank between the swages I and J, while still confined in the diebox. The second cam M, Fig. 23, upon the cam shaft O, now draws down the other crosshead N, in which is fixed the punch D, Fig. 25, for perforating the blank. The cams H and M are so shaped that the punch is made to pass down through the blank and out again, before the blank is relieved from the pressure of the swages; so that the metal is strongly compressed both before the punching and during the whole time the punching is being performed. After the punch has been withdrawn, the diebox C is carried up again by the return motion of the cam H; and the finished nut being tight in the diebox would be carried up with it, but the swage I is prevented from rising through more than half the stroke of the diebox, by means of the set screw P, Fig. 24, which stops the ascent of the check piece L. The nut is thus pushed out of the diebox by the swage I, and is ready to be knocked off by the revolving arm G, Fig. 23, which is driven by bevil wheels from the cam shaft O.

The dies, swages, and punch are so fixed to the machine that they can easily be removed and replaced by others of different sizes: by this means the same machine may be used for making nuts of various sizes and shapes. Two of these machines have now been at work at the writer's works in Manchester for upwards of five years. With the aid of a good furnace, from 15 to 20 cwts. of $\frac{7}{8}$ or 1 inch nuts can be produced in a working day of 10 hours, the machine running at 60 revolutions per minute. All the nuts possess the same degree of accuracy in shape, the sides being parallel to each other, and the hole being punched perfectly central whilst the nut is under pressure in the diebox. The iron is fed into the machine at a welding heat, and the pressure put upon it by the swages in the diebox has the effect of closing up the fibres of the iron, as seen in the samples exhibited, making the nuts very much stronger than those forged in the ordinary way by hand. The holes punched are perfectly clean and regular, and have no scale inside them to injure or chafe the threads of the taps, when being screwed.

A Bolt Heading Machine, similar in some of its principal parts to the nut making machine just described, is shown in Figs. 26 and 27, Plates 70 and 71. Fig. 26 is a general plan of the machine, and Fig. 27 is a sectional plan to a larger scale, showing the arrangement and operation of the dies and the heading swage. The dies A and B, Fig. 27, which enclose the long end of the bolt C to be headed, are divided longitudinally down the centre, one half A being carried by the stationary brackets D, and the other half B by the shearing slide E, to which a reciprocating motion is given by the cam F, Fig. 26. At the outer end of the stationary die A is fixed a steel cutter I of exactly the same form as the die A; and in a similar position in the shearing slide E is a corresponding steel cutter J, projecting for the purpose of cutting off from the bar of iron the length C for making the bolt. The dies A and B are made in short lengths, so that the total length can be increased or diminished by inserting pieces of different thickness, whereby bolts can be made of any length from 1 up to 12 inches; the remainder of the space being filled up by packing pieces, and the whole firmly held together by the bolts G.

The bar of iron for forming the bolt C, Fig. 27, heated to a welding state for a short distance only at the end, and of the same diameter as the screwed portion of the bolt, is inserted between the dies A and B while open, and pushed in up to the heading swage H, the length of which is adjustable so as to measure off the iron to the correct length for making bolts with different thicknesses of head. As soon as the bar is inserted between the dies, the shearing slide E carrying the die B and cutter J being pressed forwards by the cam F cuts off the length C for forming the bolt; the cutter and die B then remain stationary in this position and hold the bolt C firmly between the dies A and B until the formation of the head is completed. The diebox K is now moved forwards by the cams L and slide M, until it touches the face of the dies A B; when immediately the centre ram N carrying the heading swage H is advanced by the cam O, and compresses the heated metal so as to fill the diebox K and form the bolt head. The

heading swage H then remains stationary whilst the diebox K is drawn back clear of the bolt head, when the swage also retires to its original position. The shearing slide E is then withdrawn by the cam F, leaving the bolt C in the stationary half A of the dies: and a moulder P actuated by a cam at the side of the large wheel R, Fig 20, strikes the finished bolt, and discharges it from the dies.

This machine makes about 80 strokes per minute, and is capable of producing a bolt at each stroke, provided it be supplied with the iron at a proper heat. The bar of iron is heated only at that portion which is to form the head, the remainder or bolt end being out of cold. The object of this is to prevent the bolts from being scaled their whole length through the action of the fire. Some sample bolts made by one of these machines are exhibited to the meeting. The ram N carrying the heading swage H is acted upon by the cam O through the intervention of a lever S, through which the whole pressure is transmitted: and the bottom end of this lever is centred upon an oak beam fixed inside the framing of the machine, which being slightly elastic prevents the machine from being broken in the event of more iron being inserted into it than is required to make the bolt head. In consequence of this provision a bolt has been made without breaking the machine with a head as much as $1\frac{1}{4}$ inch thick, when the dies were set to make it only $\frac{3}{4}$ inch wide: this bolt is also exhibited to the meeting.

There are a great variety of special tools, for railway and machine-making purposes, which the writer has been obliged to pass over, and which would form ample material for another paper.

In conclusion it may be remarked that the opinion is now universal, that without extraordinary strength, rigidity, and power in tools, their work cannot be accomplished either quickly or well. Accuracy in the manufacture of tools and their universal application have had a great effect in the perfection of the work executed and in the facility and economy of its performance. By the assistance of gauges for different parts of machinery, the advantages of engineering tools have been more fully realised: and no engineering

work of whatever magnitude need now remain unaccomplished for want of tools.

Notwithstanding the length of time during which the improvement of tools has been in progress, and the great advance that has been made, it may be said that at the present time there is a wider field for improvement than ever, and a constant and increasing demand for tools of novel construction for special purposes.

The PRESIDENT remarked that they were greatly indebted to Mr. Fletcher for his very interesting paper just read, which had been kindly prepared by him, as one of the oldest manufacturers of heavy engineering tools in the country, in compliance with the special request of the Local Committee, for the occasion of the present meeting of the Institution in Glasgow.

He enquired respecting the nut making machine described in the paper, what quantity of nuts was produced by the machine in regular work before the punch and diebox required facing up again, and whether the punch and diebox did not get hot in working.

Mr. FLETCHER replied that the punch and die generally required facing up about once a day, and lasted about six or seven months in almost constant use before requiring to be replaced: they produced on the average about a ton of nuts without facing up. A large jet of cold water was kept constantly playing upon the punch to prevent its becoming hot; and with the machine running at the speed of 60 to 70 revolutions per minute, the time that the heated metal was in the diebox was so short that it scarcely produced any effect in heating the dies. At first the machine had been run at 30 to 40 strokes per minute, but the speed was afterwards increased to 50 and then to 70 revolutions per minute, as it was found the faster it was driven the better was the diebox kept from heating. Beyond 70 revolutions per minute however he did not think the workman could keep up with the feeding, which had to be learned by practice, the same as in working other machines running at high speeds.

The bar of iron from which the nuts were made had to be turned over at each time of feeding, because the diebox in shearing off the piece of iron to form the nut bevilled the edge of the iron a little ; but by turning it over each time the bevil was reversed for the next nut, and the nuts were thus made all sound and solid throughout without any deficiency of metal or any imperfect places upon the external surfaces. The workman soon became expert by practice in turning the bar of iron and feeding the machine with perfect regularity up to the speed of about 70 revolutions per minute.

The PRESIDENT enquired whether the common iron was found good enough to make nuts from by the machine.

Mr. FLETCHER exhibited some specimens of the nuts made by the machine from common iron, which had been split open afterwards by a taper punch for the purpose of showing the nature of the fracture, and it was seen in all of these that the metal was closely compressed and condensed and made thoroughly sound in the process of forming the nut. The hot iron blank was confined in the diebox and compressed by a heavy pressure during the operation of punching out the bolt hole, and it was found that by this means the nuts made by the machine from common iron were as strong as nuts made from best iron punched in the ordinary way. Some of these nut making machines had now been at work in Glasgow for several years.

Mr. W. McLELLAN said he had two of the nut making machines now at work, which had been working regularly for about two years in Glasgow, and were found to answer very well indeed. In first beginning to work them, the machines had been driven at only about 50 revolutions per minute, as it was feared the workman would not be able to feed at a higher speed : afterwards however the speed was increased to 60 revolutions per minute, at which the machine was found to work better ; the tools lasted longer, without so many breakages as at the lower speed of 50 revolutions. With regard to facing the dies, he had found they would work considerably longer than had been stated before requiring facing up, for the machines at his works had turned out as much as $2\frac{1}{2}$ tons of nuts each with one set of dies without facing up.

Mr. J. KENNAN enquired what metal the dies were made of in the nut making machine, whether steel or chilled cast iron.

Mr. FLETCHER replied that he had used chilled cast iron, malleable cast iron, and steel for the dieboxes, and had found that ordinary cast iron chilled was about the best material for the purpose; the swages and punch working through the diebox had never been made of anything but steel.

Mr. H. MAUDSLAY remarked that the gradual introduction of drilling machines during the last few years for making the rivet holes in plates of girders and bridge work generally, in place of punching them as formerly, appeared to be attributed in the paper just read to the defective character of the work performed by the punching machine, and the difficulty of getting a good joint with two punched plates rivetted together. This however he thought was not the case; and when it was considered that the punching machine, since its invention as a self-adjusting and self-feeding machine by the late Henry Maudslay some forty years ago, had been increasingly employed for all rivetted work, and had been adopted for iron shipbuilding purposes in all the dockyards in the country, while it was also employed at the present time in the manufacture of steam boilers for working at pressures up to 250 lbs. per square inch, he thought the modern practice of drilling the rivet holes for bridge work could not be accounted for by the workmanship produced by the punching machine being inferior. The real reason he believed was to be found in the circumstance that in ordinary boiler work there were only two plates to be rivetted together, with a lap joint, and the rivet holes were all along the edges of the plates; but in the present construction of large plate-iron girders, where the thickness of the girder was made up by four or five plates rivetted together with butt joints, the plates were arranged to break joint with one another, so that there should not be more than one butt joint at any one place; and consequently the rivet holes came in all positions in the plates, from the edges to the centre, and no punching machine that had ever been made would be large enough to take in all the plates, for punching through all the thicknesses simultaneously, nor could

the plates be punched separately with sufficient regularity in the position of the holes for enabling them to come together afterwards with the perfect accuracy necessary in that description of work. It was therefore inevitable to resort to drilling for that sort of work, in order to have the means of making the holes in any position in the plates, and with such regularity that they should correspond with perfect accuracy throughout the whole series of plates.

Mr. FLETCHER explained that in alluding to the defective workmanship of punching machines for making rivet holes he had referred only to the case of wrought iron bridge building, where girders were composed of a number of thicknesses of plates rivetted together. If punched holes were employed in that description of work, they were inevitably made slightly tapering by the process of punching; and when five or six punched plates were brought together for rivetting up, the rivet could only be made to fill the holes in the two outside plates, and merely passed through the inside plates, without touching them except just at the smallest part of the hole. For ordinary boiler making and similar purposes, where there were only two plates to be rivetted together, it was perhaps possible that punched holes might make a stronger joint than drilling, if care was taken to punch the holes the right way and then put the plates together with the small ends of the holes next to each other; but even then the holes would not be any better filled by the rivets than they would be if made by drilling, and drilling gave the means of filling the holes completely by the rivets through any number of plates that had to be put together. But as to injuring the quality of the iron round the hole, there was no doubt that punching must do so to some extent, by the splitting strain put upon the metal by the punch; and this was clearly shown by cutting open plates rivetted with punched holes and with drilled holes, when the difference in the state of the metal round the holes in the two cases was plainly seen.

The PRESIDENT enquired whether any difficulty had been found in the multiple drilling machine, from the drills not working equally after they had worked a length of time, and thereby not drilling the holes with the required accuracy in the plates.

Mr. FLETCHER replied that there had not been the slightest difficulty from that cause, and the whole of the work done by the drilling machine was so uniform that the plates were put together indiscriminately with perfect accuracy. He had seen a girder some time ago at Messrs. Kennard's works at Crumlin, in which there were four thicknesses of plate in the flanges and six thicknesses at the joints, all with holes drilled by one of these machines, put together ready for rivetting up; and in walking over a length of 200 feet along the top of the girder with an iron rod turned to the size of the drilled holes, he had been able to drop the rod easily through all the four or six thicknesses of plates at every hole that he had tried. The saving of time therefore in putting such a girder together and rivetting up must be very great indeed as compared with a girder constructed of punched plates. In making the holes in the plates he did not think there would be much difference in time between punching and drilling; and in respect of cost, probably drilling would be cheaper than punching, where there was a large quantity of work to be done and a set of men properly trained to it. There could be no question therefore, he considered, that in bridge work especially drilling was far superior to punching for the rivet holes. In the multiple drilling machine shown in the drawings, the plates to be drilled were placed on a stage close by the machine, ready to be slid upon the drill table; one man and a boy attended the machine, and put the plate on and removed it when drilled. During the drilling the plate was entirely immersed in soap and water, in which the drills worked; and if anything went wrong, the drill table was let down immediately by shutting off the water pressure from the accumulator, and was afterwards raised up again to its work with the greatest readiness by turning on the pressure again.

Mr. J. VERNON remarked that at the Liverpool meeting of the Institution in last year he had exhibited some specimens of plate that had been rivetted together with punched holes and with drilled holes, and had been afterwards cut open down the centre of the rivets so as to show in both cases how the rivets filled the holes; and it was then clearly seen that the rivets filled the punched holes

as perfectly as they did the drilled holes. From his own experience also he fully concurred in the opinion that it was not because work was unsound and imperfect when done with punched holes that drilling was required to be resorted to: drilling had its advantages and might be largely applied; but it was not the case, he believed, that punched work when carefully prepared was imperfect or inferior work. With respect to accuracy in the position of the holes, he thought as great accuracy might be attained with punched holes as with drilled holes; and he had had a punching machine in operation at his own works for several years past, which was capable by a self-acting motion of punching a whole boiler plate throughout every part with as complete accuracy as could be attained in any drilled work that could be produced.

Mr. D. ADAMSON observed that, having had frequent opportunities of witnessing the testing of high pressure steam boilers, sometimes with punched rivet holes and sometimes with drilled holes, he had come to the conclusion that no one who had had experience of drilled holes in that particular class of work would be likely to attempt to use punched holes again for such purposes. However carefully a punching machine might be arranged, and however well the work might be put together, there still remained the objection which had been mentioned, that the punched holes were always conical, rendering it a difficulty to fill the holes completely in hand rivetting. Several boiler explosions which he had seen might be entirely attributed, he believed, to that class of bad work. In the case of an explosion that occurred some years ago at Huddersfield, he had examined the boiler afterwards, and had not found a single instance in which the rivet filled the rivet hole completely from one side of the plate to the other, and there were very few rivet holes that were at right angles to the plates, the rivetting being exceedingly bad and the punching exceedingly bad also. In punching holes too much depended on the care exercised by the workman, and he had found that boiler plates punched on Monday were not done so well as those punched later in the week, from the men not being so careful and accurate on the first day of their week's work as they were afterwards when they had got more

into it. It was therefore very desirable to take it out of the power of the men to produce defective work ; and he had accordingly adopted the plan of not only drilling the holes in all boiler plates that were to be subjected to a high pressure, but also drilling the two plates together in the position in which they were to be rivetted up, in order to allow correctly for the curvature of the plates ; so that it should be impossible for the workman to produce irregular holes, and that when the plates were rivetted together all the holes should coincide exactly, and every rivet should take its proper share of the strain.

In the case of the longitudinal seams of large boilers, say 6 feet diameter made of 9-16ths inch plates to carry 100 lbs. steam, he considered the single rivetted joint with punched holes was exceedingly unsafe on account of the great shearing strain to which the rivets were subjected. Moreover although in a single test such a boiler might appear tight up to the testing pressure, it would be found that by afterwards raising the pressure again rapidly up to the testing amount the joints would not be tight in the second test, but would exhibit a slight leakage or sweating in many places, which would be continued and increased in any subsequent testing when the pressure was raised quickly. It was therefore not sufficient to try boilers by a single test, but a prolonged trial was necessary, repeating the test say fifty times in a day with intervals ; and having adopted this mode of testing he had found that, in testing punched boilers for a day together, every time the pressure was put on there was more or less trickling from the joints ; but with drilled holes the work was much more to be depended upon, and there was less of the ordinary sweating at the joints, nor was any serious leakage ever produced by repeatedly putting up the pressure rapidly. Hence for locomotive boilers especially, subjected as they were to such rapid variations of pressure, it appeared highly desirable that all the rivet holes should be drilled, and also that the two plates should be drilled both together in the position in which they were to be rivetted.

In boilers of very large diameter, such as 7 feet diameter with plates $\frac{8}{4}$ inch thick, single-rivetted joints became impracticable,

whether the holes were drilled or punched; because the extra thickness at the lap of the joint threw the plates so much out of the true circle that every time the pressure came upon them it sprung the joint with a force which inevitably produced leakage when only a single row of rivets was used. No doubt a great deal of the external corrosion observed in boilers was due to the continual small leakages produced in this way by the variations of pressure. But a more serious evil, especially in locomotive boilers, was that this constant springing of the joint had ultimately the effect of exfoliating the interior surface of the plates all along the seam; and the iron became guttered along the edges of the plates to such a depth through the thickness of the metal that in some cases locomotive boilers had exploded whilst working at no higher than the ordinary pressure.

It was true that in rivetting up punched work with the steam or power rivetting machine the rivets might be made to fill the holes, but it did not follow that work so put together was as strong as if the holes had been drilled; for on planing open the joint in the punched work it would be found that there was more or less irregularity in the holes, and therefore the rivets would not all of them take their proper share of the strain along the whole length of the joint. But when drilling was used and all the holes were drilled exactly at right angles to the plates, and when the rivets were made in accurate dies so as to contain all the same amount of metal, and were afterwards put in the holes by a power rivetting machine, a joint was ensured which probably no rivetting would be able to excel. So satisfied was he of the advantages of drilling over punching, in the greater security and tighter work obtained with drilled holes, especially in the case of boiler work, that he hoped in a short time to carry out drilling exclusively at his own works, and to abandon punched holes altogether for any description of work whatever. A still further step remained in reference to the longitudinal seams of boilers, which would be to weld up the plates along the joint, so as to avoid having any rivetted joint for such cases; and he had been led to conclude that this would prove the only ultimately satisfactory plan, as he considered more

confidence was to be placed in the welded joint than in the best rivetted joint even with drilled holes.

Mr. T. FLEET considered that, when punching was done carefully and accurately, as good and sound work could be produced with punched holes as with drilled holes. It appeared to be thought that in drilling there was not so much liability to want of uniformity in the holes as in punching; but in the multiple drilling machine shown in the drawings, if the drills were not all set perfectly true in their correct positions and exactly upright, the drilled holes would be no more regularly spaced and no more truly at right angles to the plates than punched holes done by a good workman. Moreover if the drills were not properly looked after by the man attending the machine, he might as easily cause defective work to be turned out as a man setting plates in a punching machine. No doubt workmen were apt to be not so efficient at their work in the beginning of the week as afterwards; but that was a matter which rested with the masters and foremen, and no work of an inferior description ought to be allowed under any pretext. It was certainly the case that in punched holes there was a little taper; but by properly proportioning the size of the punch and of the hole in the die, the degree of taper might be reduced to so small an amount as not to be injurious; and if two punched plates were put together with the smaller ends of the holes next each other, the work would be made as good as it was possible for it to be. He had had rivetted joints planed through down to the rivets for the sake of trial, and had found the punched holes were as well filled by the rivets and the work was as good and sound as when the holes were drilled. It was only within the last few years that the question of drilling the holes for boiler plates had been raised; and for many years previously boilers with punched holes had been made tight and fit for service, and were still made so, nor had he known of an explosion occurring with any boilers made with properly punched holes. As regarded rivetting more than two thicknesses of plates together in bridge work, which had been said to be not so safe with punched holes as with drilled holes, he had not found any deficiency of strength with punched holes, even

in rivetting as many as four or five thicknesses of plates together up to a total thickness of $3\frac{1}{2}$ or 4 inches ; and in all such cases the work so put together with punched holes had stood the testing without any difficulty, and had proved thoroughly sound and strong for the purposes intended.

In reference to the use of steam rivetting machines for putting in the rivets instead of hand rivetting, that question had been considered at the time of building the Britannia Bridge, in the rivetting work of which he had been engaged ; because it was then thought that hand rivetting would not be sufficiently good for that class of work. Wrought iron bridge building being then in its infancy, a trial was made of the comparative value of the machine rivetting and hand rivetting, by cutting out a number of rivets put in by the two methods ; and it was found that in the work done by the steam rivetting machine the holes were not filled up so well as by hand rivetting, and the rivets put in by hand took about ten or twelve more blows to knock them out with the hammer than those put in by the machine : the bridge was accordingly completed with hand rivetting. Moreover in rivetting by machinery, both in boiler making and in bridge work, if the plates were not brought perfectly close together at the time of rivetting, when the blow came on the rivet it formed a sort of washer between the plates, which prevented their ever being closed up afterwards ; but in hand rivetting a good rivetter took care to drive the rivet fairly into the hole and close the plates with the hammer at the same time that he was finishing the rivet, so that the contraction in cooling should make a perfectly tight joint.

The PRESIDENT enquired how the spur mitre wheels driving the drill spindles in the multiple drilling machine were found to wear, and whether malleable cast iron had been tried for the purpose.

Mr. FLETCHER replied that these spur mitre wheels were found to wear very well indeed ; he exhibited some of them made of cast iron, which had been working constantly in one of the drilling machines ever since it was started nearly twelve months ago, and they scarcely showed any signs of wear at all. Some of the wheels on the horizontal driving shaft had been broken occasionally, in

consequence of having the centre hole too large ; these had broken through just at the key groove, owing to the drill happening to break just at the moment of going through the plate, which was liable to occur now and then. He had tried malleable cast iron for the wheels, but found it would wear too fast ; and the wheels were now made therefore of cast steel, of which specimens were exhibited, in order to obtain greater strength, and he had never had any of the cast steel wheels broken in the machine. When only a single horizontal driving shaft was used, having some 50 wheels keyed on it for driving the drills, the torsion was of course very great, and a large diameter of shaft was required to give sufficient strength ; but by the improved plan of using two horizontal driving shafts, driving the alternate drill spindles, each shaft had only half the work to do, and a smaller size of shaft could therefore be used. The shafts were made of cast steel, and he had also driven each shaft at both ends ; but the torsion was still considerable in the middle of the length, and caused the skew wheels to rattle a little in working, as the drills cut harder or easier in the metal.

Mr. J. J. BIRCKEL enquired why the skew mitre wheels employed in the drilling machine had been applied for driving the drill spindles in place of ordinary mitre wheels. He thought there must be much more friction with the skew wheels than with ordinary mitre wheels, since in the latter the friction was more of the nature of rolling friction.

Mr. FLETCHER explained that the object of adopting the skew wheels instead of ordinary mitre wheels for driving the drill spindles had been that the horizontal driving shaft might be kept out of the way, behind the drill spindles, so as to allow of getting a good strong tail piece with set screw at the top of the drill spindles, for receiving the heavy upward pressure on the drills in working. This could not have been managed with mitre wheels and the longitudinal shaft overhead.

Mr. J. KENNAN enquired whether there was not some difficulty from the end pressure on the horizontal shaft driving the drill spindles, owing to the inclination of the teeth of the skew wheels ; and he suggested that the teeth might be inclined at opposite

angles alternately right and left in the successive wheels, so as to neutralise the end pressure on the driving shaft.

Mr. FLETCHER said there was no end pressure at all on the horizontal driving shaft, as each of the skew wheels on the shaft worked between two end bearings in its own drill frame, which received the end pressure instead of the shaft.

The PRESIDENT enquired whether the parallel motion was found to answer satisfactorily the purpose of keeping the drill table level in working.

Mr. FLETCHER said the parallel motion formed by the pair of racks and toothed segments coupled together at each end of the drill table had been found a great improvement in the multiple drilling machine. Previously it had been necessary to place a block of wood on each side of the drill table, as a stop to limit its height of rising and prevent it from canting in case the drills on one side of the machine should come through the work sooner than those on the other side. But with the addition of the parallel motion there was not the slightest deviation from level in the table, either sideways or endways, at whatever part of the table the pressure of the drills might be acting; and it was thus of great advantage in preventing any undue pressure from some of the drills getting through the plate before others.

Mr. J. KENNAN asked whether any trials had been made with different forms of drill points, and what form of point had been found the best.

Mr. FLETCHER replied that he had tried several forms of drill points, but found there was the least trouble with the ordinary shape of point, such as was shown in the drawings and in the specimens of drills now exhibited. The speed of drilling might be increased by putting extra pressure on the drills, and by that means he had drilled through $\frac{3}{4}$ inch plates in as little as $3\frac{1}{2}$ minutes; but this rate was not necessary in ordinary work, and such plates generally took about 10 minutes to drill through.

Mr. W. M. NEILSON enquired whether the drills were ground up by hand, and how the grinding was done so as to keep them all uniform.

Mr. FLETCHER replied that the drills were all ground up by hand to a gauge, so as to be all exactly the same diameter and form. The drills were carried in cylindrical sockets and fixed by set screws, allowing of their being adjusted to a constant length when shortened by grinding. At Messrs. Kennard's works at Crumlin there were six of the large multiple drilling machines, and two smaller ones, and one man was employed in grinding up the drills for the whole of the machines, to keep them all uniform.

Mr. W. RICHARDSON enquired whether there was not some difficulty with the drilling machine at the moment of the drills going through the plate, on account of the drill table being forced up against the drills by the constant pressure of the accumulator. He thought when the drills were just going through, the table would rise too fast, and be apt to break the drills by the side strain put upon them from suddenly losing the resistance of the cut.

Mr. FLETCHER said that when the drills were beginning to come through the plate the workman could hear it directly, and could ease off the water pressure a little if desired, by partly closing the valve from the accumulator: but it was scarcely ever necessary to do that, and there was very little trouble from the drills breaking at the moment of going through. The drills were made pretty stiff, and very short from the bearing in the drill socket, so as not to be easily broken.

Mr. W. FORD SMITH asked how the drill spindles were set in the machine with sufficient accuracy at the exact distance or pitch from centre to centre. In the case of the transverse joints of cylindrical boilers, for instance, the outer plate lapping over the inner was of course a little longer; and having the same number of rivet holes would require the holes spacing rather wider apart all round the circle, so as to correspond with the holes in the inner plate. It had been proposed to drill the holes in the two plates together for boiler work; but though that might be done for the longitudinal joints, it could not be managed in the transverse joints from the difference in the length of the two plates.

Mr. FLETCHER explained that the drill spindles were all turned accurately to 2 inches external diameter at the bottom or drill

socket, and were set up one after another by inserting a template of the required size between. Thus for drilling holes at 3 inches pitch a template of exactly 1 inch width was put between the drill spindles; and supposing this were the pitch for the rivet holes in the inner plate of a transverse boiler seam, and the outer plate were $1\frac{1}{2}$ inch longer, the extra $1\frac{1}{2}$ inch was divided out equally between the entire number of holes by using a slightly larger template made to the exact size required. As there were two rows of drills in the machine, the best plan in such work was to set one row for drilling the inner plates and the other for drilling the outer plates, so that the drilling of both plates should be proceeded with simultaneously.

Mr. D. ADAMSON thought that plan would still not be so satisfactory as drilling both the plates together, as they were to go in rivetting; and even in the case of the transverse joints of boilers it was highly desirable that this should be managed, by bending the plates beforehand and then drilling them together solid when bent, so as not to have to disturb the iron in any way by bending after drilling. The great advantage of such a method was that the very same drill passed through both plates, and therefore any slight variation in the size of the drill used did not affect the accuracy and solidity of the work for rivetting up, and the hole was perfectly cylindrical through both plates. This could not be said however of plates drilled separately while flat and afterwards bent to the required curve.

Mr. FLETCHER had not found any inaccuracy arise from drilling the plates separately instead of together, or from bending the plates after drilling them flat. In plates 5-16ths or 3-8ths inch thick the alteration in the holes by bending the plates after the drilling was so inappreciable that a turned pin could be passed through the holes in such work with as great facility as in the case of the flat plates drilled for bridge work, which he had already mentioned. He therefore thought drilling the plates together after bending was scarcely necessary for practical purposes.

Mr. J. MANNING said he was now making a self-acting punching machine for punching flat plates independent of manual labour, with an adjustable rack motion for shifting the plate and spacing out the

holes, and a variable curvilinear movement for punching the circular lines of rivet holes in the end plates of boilers for the shells or the internal flues. A dividing scale was also added for making the proper alteration in the pitch of the holes in the outer and inner plates, in punching the rivet holes for the circular seams of the boiler shell. He was not aware whether this had been managed yet in punching machines, and thought if successfully carried out with the required degree of accuracy it would go far towards removing the objections entertained against punched boiler work.

Mr. J. VERNON enquired whether the use of separate engines, one to each machine, for driving a number of separate machines doing a variety of work, as in the case of iron shipbuilding, was considered to be under all circumstances a more advantageous and economical application of steam power than driving the same machines by a line of shafting and belts. Supposing there were a dozen large machines in the same workshop, which were all required to be worked constantly the whole day through, he presumed it would not be considered better in that case to use separate engines for each machine than to employ one engine for driving the whole lot of machines by shafting.

Mr. FLETCHER said that in the latter case, having a number of machines that were all kept constantly at work, and where the work could be kept close to the machines without having to be frequently taken out of the shop and brought back again, the single large engine with shafting to drive all the machines was no doubt the best. But whenever, in the case of shipbuilding and similar work, it occurred that plates had to be carried backwards and forwards a considerable distance, merely for punching a few more holes or doing some other small work upon them, it was then found much better and cheaper to take one or two machines down to the spot and do the work there: and it was for such purposes as these that machines were now made to be driven each by its own separate engine.

Mr. NEIL ROBSON enquired whether any difficulty was found in conveying the steam to a distance for working separate machines,

owing to leakage at the joints of the steam pipe. He had himself found great difficulty in keeping the joints tight, particularly in one instance where the steam was conveyed as far as 400 yards in a straight line of pipe, in which case he had got over the difficulty by making two expansion joints in that length: and he asked what was the greatest distance to which steam had been conveyed from a boiler for working an engine or machine.

Mr. FLETCHER replied that the difficulty with the joints of the steam pipe in such cases arose from having the pipe in a straight line for the whole distance, without any curves; but if there were a few curves inserted in the length of the pipe, these would allow for the expansion and contraction of the line of pipe, and there would be no difficulty in keeping the joints steam-tight. Any condensation of steam that took place in the pipe might be provided for by having a low part in the pipe at the further end, with a tap to draw off the condensed water whenever desired.

Mr. D. ADAMSON said that, in regard to the distance to which steam could be carried in pipes, there was not much difficulty in conveying it even to very great distances. At one of Mr. Joseph Pease's collieries near Darlington, where the whole of the water was originally pumped by engines at the surface, it was afterwards desired to work a lower portion of the mine, for which purpose a pumping engine was placed down in the pit, and was at first supplied with steam by boilers alongside in the pit. The water pumped from the mine however was so corrosive and destructive to the boilers in the pit, that it was ultimately found necessary to abandon them and to take steam from the boilers at the surface. The distance the steam had to be conveyed by pipes in that instance was very great indeed: the pit was about 120 yards deep, and the underground engine was about $\frac{3}{4}$ mile from the bottom of the pit, making altogether about 1440 yards distance that the steam was carried; notwithstanding which the work done by the engine per pound of coal consumed under the boilers was very nearly equal to what it had been when the boilers were down in the pit close to the engine. It appeared therefore there was no reason to anticipate any difficulty in merely distributing steam by means of pipes to the comparatively

short distances necessary for working detached machines in a shipbuilding yard or similar cases. In the instance that he had described, a large branch syphon pipe was connected to the steam pipe at the further end, close to the engine, in which the condensed water collected and was drawn off at intervals, while the steam passed along the straight pipe direct into the engine.

Mr. J. J. BIRCKEL mentioned that in preparing the plates for the construction of the Great Eastern ship the edges of the plates had not been planed, but shaped in a circular shaping machine which he believed was similar to a facing lathe.

Mr. FLETCHER said he had made a number of machines of that description for shaping the edges of plates instead of planing them in an ordinary planing machine. The machine had a large disc about 6 feet diameter, revolving on a horizontal shaft, and in the face of the disc were fixed a set of about 36 cutters, across which the plates to be shaped were traversed on a horizontal sliding table. Three of these machines were at work at the Crumlin Works, where they were employed in shaping the edges of plates, instead of planing them by the planing machine as usual.

The PRESIDENT remarked that he had had disc machines of that description in operation at his own works for the last thirty years, and they were used for cutting the inside of sheer strakes in shipbuilding and for similar purposes. He enquired which plan was considered the best, the disc machine or the ordinary planing machine.

Mr. FLETCHER replied that where there were a great number of plates to be shaped to the same size or pattern, as in bridge work or shipbuilding, he thought the circular disc with cutters would be found more expeditious than a planing machine. For with the disc machine a number of plates could be clamped together and brought up on a truck and laid on the table of the machine, which could then be left to do the work with only a boy to mind it for two or three hours ; but with a planing machine the men were continually occupied in bringing up one or two plates to be planed at a time. By means of the disc machine, as much as 3 feet thickness of plates had been shaped at once in the case of the plates for the Great

Eastern ; and the machines at Crumlin shaped 18 inches thickness of plates or upwards in ordinary work.

MR. W. FORD SMITH remarked that the angle of 85° adopted for the **V** grooves in the tables of planing machines appeared to him rather more acute than was desirable or necessary, since the friction was of course greater with an acute angle than with one more obtuse, requiring therefore greater power to drive the table with the acute **V**s ; and it was also desirable, in order that the **V**s might keep in good order, to get as wide a bearing surface as possible, so as to reduce as far as practicable the pressure per square inch and consequently the friction and liability to galling. He had accordingly adopted a considerably wider groove for such purposes, with an angle of 120° ; and he had not found any difficulty from the table of the machine ever rising up the sides of the **V**s made with that inclination, and thought the surfaces of the grooves wore better than if made more acute. For oiling the **V**s the ordinary plan was to fill the channel at the bottom of the groove with oil, which was then raised by agitators and spread over the sides of the groove by the motion of the sliding table ; but as any dust and cuttings falling into the grooves would collect in the channel at the bottom and be mixed with the oil, he thought it was better to oil the grooves by a channel at the top along each side of the groove, filled with pure oil by self-acting lubricators, by which a small quantity of oil would be caused to flow over down the sides of the groove ; and the oil should be swept off into pockets at the ends of the **V**s by each traverse of the table, instead of being allowed to lie in the bottoms of the grooves. By this plan combined with the increased surface of wider **V**s there would be less liability to the surfaces galling in working.

With regard to the use of the rack motion for sliding the table in planing machines, no doubt the use of the pinion of large diameter gearing into the rack was a great improvement in principle upon the ordinary small pinion, since with the large pinion there was less tendency to lift the table. But in reference to the employment of stepped teeth for the rack and pinion, in place of the ordinary single teeth, he had not found it practicable to produce castings of stepped

racks and pinions so accurately spaced throughout as to ensure all the teeth taking their proper share of the work ; the whole strain of the driving power, instead of being borne by the entire width of the rack, had consequently to be borne only by the portion of the width that happened to be actually in contact, and hence breakages were liable to take place. He had accordingly been led to adopt plain racks, not stepped, with pinions of large diameter, for traversing the tables in planing machines and similar cases ; and the results had proved thoroughly successful, not only in preventing breakages, but also in producing good planed surfaces, perfectly free from jars and teeth marks.

Mr. FLETCHER said that with regard to the angle of the **V** grooves in the planing machines he had not found any tendency to galling of the surfaces with the inclination of 85° that he had adopted ; one machine that he had made twenty years ago with **V**s of that angle had been doing work of the heaviest and roughest description ever since at Messrs. Napier's works, and he had no doubt it would be found on comparison that the surfaces of the grooves were now in better condition than would be the case he believed in any machines with wider **V**s after working for the same length of time. The plan that had been mentioned of oiling the **V**s by a channel of oil at the top, along each side of the groove, had the objection that the machine would then require oiling many times in a day ; whereas with the ordinary plan of oiling, by keeping the supply of oil in the bottom of the **V**, the machine need not be oiled more than once in three or four days.

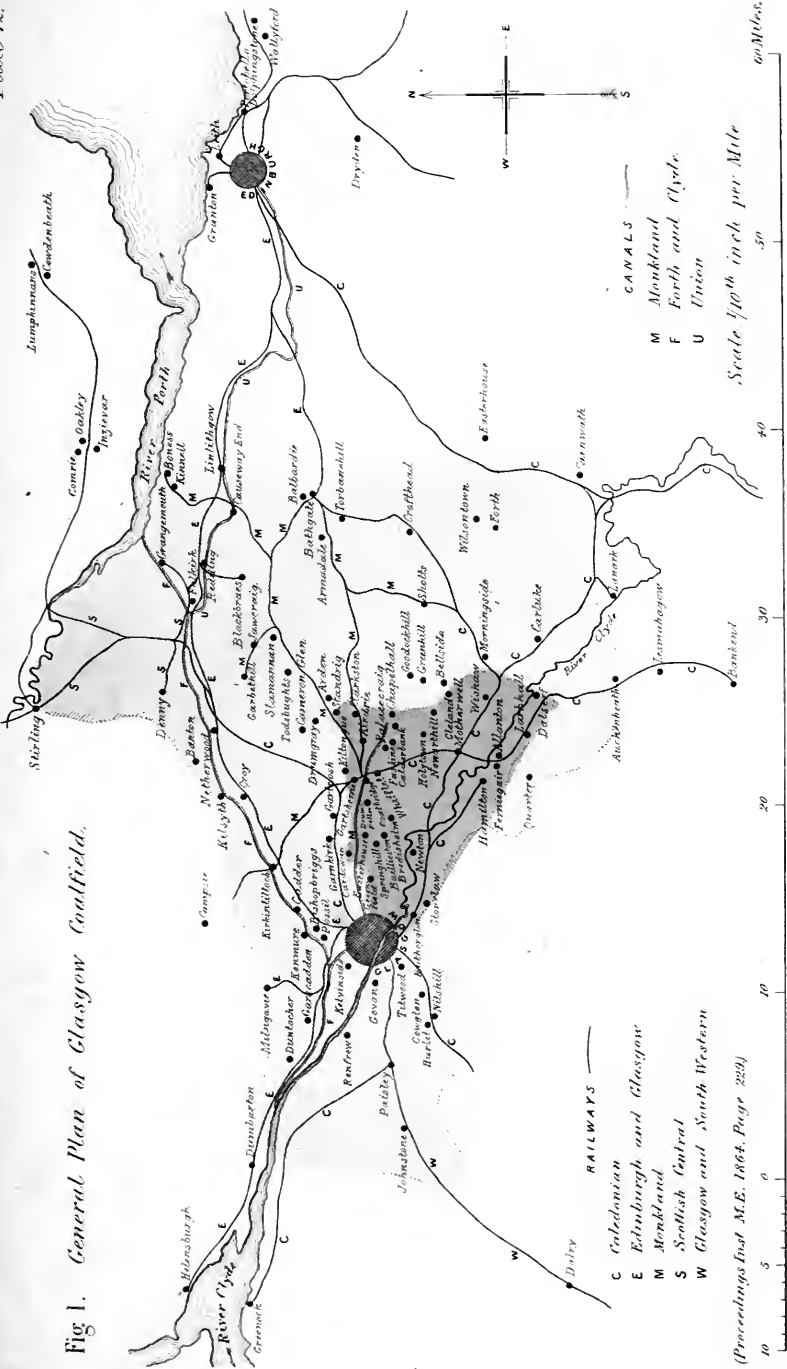

In reference to the stepped rack for driving the tables of planing and other machines, he believed the rack motion was more generally used for such purposes than the screw, and he had adopted the rack exclusively for the last twenty or thirty years as the most eligible arrangement ; nor had he found any such difficulty as had been referred to in practically attaining sufficient accuracy in the teeth. He was confident that if any well made machine worked by the stepped rack motion were examined only a couple of hours after it was first put to work, before it had even completed planing its own

table, it would be found that all the teeth had got into efficient driving contact.

The PRESIDENT moved a vote of thanks to Mr. Fletcher for his paper, which was passed.

The following paper, communicated through the President, was then read :—

ON THE PRINCIPAL SEAMS OF COAL AND IRONSTONE IN THE GLASGOW COALFIELD.

BY MR. WILLIAM MOORE, OF GLASGOW.

General description of Coalfield.—The valuable seams of Coal and Ironstone in the Glasgow Coalfield are situated in the counties of Lanark, Stirling, Dumbarton, Renfrew, and Linlithgow, and lie between the New Red Sandstone and the Hurlet Coal. They are divided into an upper and a lower series of minerals: those seams lying above the Garnkirk or Caulm limestone of Garnkirk and Bedlay form the upper series; and those lying under the Possil or Cowglen limestone form the lower series. The accompanying plan, Fig. 1, Plate 72, shows the general outline and position of the Glasgow coalfield. The dark shade shows the area of the thick seams including the Splint coal and the seams above it; and the light shade shows the limit of the coalfield and the ironstone field. No portions are shown on the plan of the other adjoining coalfields of Ayrshire and Fifeshire. The positions and names of the principal coal districts are marked upon the plan within this area.

The general average section, Fig. 2, Plate 73, shows the succession of the seams from the surface, which are enumerated in the accompanying table. From this section, it will be seen that the most valuable seams of coal lie above the Garnkirk or Caulm limestone in the upper series; and that the principal seams of ironstone lie under the Possil limestone in the lower series of minerals. It is from the upper series that the coals have been taken for the supply of household, manufacturing, and ironsmelting purposes, during almost the whole history of the coalfield; and the principal seams in this series are collectively known as the Glasgow and Monkland seams, extending over an area comprising about 37 square miles, more or less interrupted by faults, bounded by

Name of Seam.	UPPER SERIES.	Thickness.	
		ft. in.	ft. in.

Bathgate and Morningside on the east, by Carluke, Hamilton, and Quarter on the south, by Glasgow on the west, and by Gartsherrie and Jaweraig on the north.

The main supply of ironstone for the use of the Scotch ironworks comes from the two Possil ironstones, the two Gartscadden Blackband ironstones, and the Dalry Blackband ironstone. These extend over the district of country indicated by the light shade on the general plan, Fig. 1.

Detailed description of Coal Seams.—The Upper coal, the first in the section, Fig. 2, is that from which Glasgow was in former years supplied with the best quality of household coal. This seam is in its best condition both in thickness and quality near Glasgow, Rutherglen, and Stonelaw. It gradually gets inferior as it goes eastward, and thins out altogether in the mineral fields near Coatbridge and Baillieston.

The Ell coal is the seam from which at present the largest quantity of coal for household purposes is derived, and which now contributes so largely to the supply of Edinburgh, Glasgow, and the north of Scotland. The most valuable deposit of this seam is in the neighbourhood of Wishaw and Motherwell, extending along the line of the Caledonian Railway nearly as far as Carluke, and on the line of the Lesmahagow branch within a short distance of Auchenheath. The thickness of the seam, which is not more than 4 feet at Glasgow and 2 feet at Baillieston, gradually increases towards Wishaw to about 11 feet. In the district adjoining Wishaw the quality is of the first class, and the coal is used chiefly for household purposes. In some of the collieries to the east of Wishaw the coal is of a slightly burnt description, and is used for steam purposes. There is still a considerable area of this seam to work, lying on the line of the railways already mentioned; in the locality immediately adjoining Wishaw however it is very much exhausted. So great has been the demand for this quality of coal for household and steam purposes, that within an area of about three square miles in the Wishaw district there are as many as twenty-five collieries working almost wholly on this Ell coal seam.

The Pyotshaw and Main coals are sometimes apart a distance varying from 6 to as much as 24 feet, as at Baillieston and Coatbridge. At Drumpeller and Wishaw they are together, forming one seam about 9 feet in thickness. The Pyotshaw coal sometimes contains a thin gas coal varying in thickness from 4 to 10 inches: at Springhill near Baillieston this gas seam is of fair quality, and is supplied to the Glasgow gas works. The Pyotshaw and Main coals are hard coals, containing rather too much ash for household use, so that they are used chiefly for ironsmelting and forge purposes.

The Humph coal is a thin seam of not much value. It has been worked at Dalmarnock near Glasgow and at Coatbridge, for furnace purposes and for calcining clayband ironstones.

The Splint coal is that which has been so long used in the manufacture of iron in the Coatbridge district. It is a hard coal of excellent quality, and in the Monkland district is very nearly exhausted. At Wishaw and in the district towards Hamilton it is entire; but it has been found very expensive to work on account of having a soft shale roof. This seam of coal is usually accompanied by a thin band of clay ironstone, varying in thickness from 3 to 4 inches, which is worked in connection with the coal. At Bredisholm near Baillieston this seam becomes a gas coal, and is worked as such to a considerable extent for the supply of Glasgow and for Irish consumption.

The Wee coal is a good household coal, and is extensively worked as such in the Baillieston district for the supply of Glasgow. The collieries working this seam lie principally along the line of the Monkland Canal, by which the coal is conveyed to Glasgow and other parts of the Clyde.

The Virtue Well coal is essentially a Monkland coal. It is found best in the neighbourhood of Airdrie and Coatbridge, and is used principally for household purposes. In some of the collieries near Airdrie the coal is burnt, and is used for steamboat purposes. In the eastern part of this seam extending to Slamannan it is called the Johnstone coal, where it is of a coarser quality and is used for household purposes.

The Kiltongue coal is worked in the neighbourhood of Coatbridge and Airdrie at a thickness of about $2\frac{1}{2}$ feet. At Drumpeller it is $6\frac{1}{2}$ feet thick, and is used for household and forge purposes. In the Redding and Slamannan districts this seam is called the Splint coal; and at Slamannan it is one of the most valuable of the Scotch steam coals, and brings the highest price on the Forth and Clyde for this purpose. At Redding the coal changes its character, and becomes a hard splint coal suitable for iron smelting purposes. Above the Splint coal at Slamannan there is a seam known as the Lady Grange seam about $2\frac{1}{2}$ feet thick, worked chiefly for household purposes. At Calderbraes, in the position which the Kiltongue coal would occupy, there is an ironstone called the Calderbraes ironstone about 8 inches thick.

The Drumgray coal is known in the Redding and Slamannan districts as the Coxrod coal. In the Airdrie and Coatbridge districts this seam is a hard furnace coal; in the Redding and Slamannan districts it is a household coal of very superior quality.

The Lower Drumgray or Lower Coxrod coal is a seam worked for household purposes; it is usually thin however, and is not generally much worked.

Besides the seams above described, which are collectively known as the Glasgow and Monkland seams, there are also several minor seams of coal in the upper series; namely those of the Bathgate, Grangemouth, and Netherwood districts; and in the lower series, the Possil, Kilsyth, Kirkintilloch, Cowglen, Titwood, Hurlet, Campsie, Duntocher, Milngavie, Auchenheath, and Lesmahagow coals. These seams however are chiefly local, worked only in the immediate districts in which they are found.

The Bathgate seams are all of such an inferior quality that they are not even worked for the supply of the immediate district. The coal used in Bathgate is principally brought from the Monkland or from the Wishaw coalfield.

The Grangemouth coals are geologically the same as those at Redding, but are a little thicker and the seams are more numerous. In point of quality the coals are not equal to those of Redding and Slamannan. The collieries however have the advantage of being

near the shipping port of Grangemouth, requiring little railway carriage, so that the inferior quality of the coals is compensated for by their cheapness, and the colliery proprietors are enabled to ship a considerable quantity of coal. The Netherwood coals are coking and smithy coals lying immediately under the Caulm limestone.

The Possil seams of coal lying in proximity to the ironstone seams are worked mainly for the supply of workmen's fires and engine fires at the collieries raising the ironstone. The Kilsyth coals are of a coking description, and are converted into coke at the collieries for the supply of Glasgow. The Kirkintilloch coals are generally steam coals.

The coals of Hurlet, Campsie, Duntocher, and Milngavie are inferior, and are used for steam purposes in those districts. The Lesmahagow and Auchenheath coal is used for the production of gas, and is the most valuable of Scotch cannels.

Detailed description of Ironstone Seams.—The Palacecraig Blackband ironstone is a seam of inferior quality, very poor and yielding only a small percentage of metallic iron. It has been worked only by the Gartsherrie Iron Company at Palacecraig near Airdrie. It extends over a large area in the Coatbridge district, but its quality has never been found such as to warrant its being much worked.

The Airdrie Blackband ironstone may be said to be almost wholly exhausted. It was upon this seam that the majority of the ironworks at Coatbridge were founded. It was discovered by the late Mr. David Mushet about the beginning of the century, and was highly valued for its freedom from deleterious impurities and for the quantity of carbonaceous matter which it contained.

The Soft Blackband ironstone resembles the Palacecraig ironstone in point of quality. It was worked near Airdrie, but was abandoned on account of its inferior quality.

The Cleland Roughband ironstone is peculiar to the mineral field around Cleland. It is a clayband yielding about 1000 calcined tons per acre.

The Bellside ironstone is found and worked in a limited area near Bellside, about $1\frac{1}{2}$ mile south east of Newarthill. It is a black-

band ironstone of good quality, and worth about 16s. per ton at the Coatbridge works. The most extensive working of this seam is at Greenhill in the parish of Shotts.

The Calderbraes ironstone is a band lying in the position of the Kiltongue coal, but not extending over a large area. It is worked at Faskine near Airdrie and at the Calderbank Iron Works. There is a thin gas coal in connection with the seam, which has recently been used for the production of paraffine oil.

The next seams are the Slaty bands of ironstone, which are the only seams lying in the upper series of minerals that are likely to yield a supply of blackband. The geological positions of these seams extend over an area equal to 30 or 40 square miles, a large part of which however is wholly unproved, while an equally large part has been proved to contain nothing beyond the mere position of the seams, the ironstones themselves being found to have thinned out. Both in thickness and quality these seams are exceedingly variable, measuring in some places as little as 4 inches thick, and in others as much as 3 or 4 feet. In its best state the quality of the ironstone is nearly equal to the Airdrie blackband; while at many places to the north of Airdrie it contains so large a proportion of sulphur as to render it quite unfit for ironmaking purposes. These bands of ironstone have been mostly worked at Bathgate, Crofthead, and Shotts. There are three slaty bands of ironstone as proved at Arden. The first of these is about 7 inches thick, and is supposed to be the same seam as that worked at Garbethill, Todsbughts, Cameron Glen, and Arden. The second or mid slaty band is about 15 inches in thickness, and is supposed to be the same ironstone as that found at Stepends, Crofthead, Armadale, and Shotts. The third band ranges in thickness from 7 inches to 4 feet, and lies in the same position as the seam at Goodockhill. In the neighbourhood of Bathgate the mid seam lies in connection with the famous Torbanehill coal, so highly valuable for the production of paraffine oil.

The next valuable seams of ironstone are those lying under the Possil or Cowglen limestone. The first of these are the Possil ironstones, two seams of excellent quality, the first of which is about 14 inches thick and the second about 10 inches, both lying in

connection with thin beds of coal, which conduces much to economy in working them. These two seams of ironstone extend over a large district, and generally maintain a regular thickness. Under the lowest of them lies the Govan gas coal, occupying the same position as the Lesmahagow and Knightswood gas coal. The quality of this coal is best and it is worked most extensively at Lesmahagow.

The next seam is the California Clayband ironstone, of good quality, and worked at Kelvinside to the west of Glasgow.

The Upper ironstone of Garscadden is the next seam; it is a blackband of first-rate quality, varying from 8 to 14 inches in thickness.

The Lower ironstone of Garscadden is very much of the same quality as the preceding; it varies in thickness from 4 to 14 inches.

The Garibaldi Clayband ironstone underlies the last mentioned seam, averaging 14 inches thick.

The Dalry or Johnstone Blackband ironstone lies under the preceding seams, varying from 10 to 18 inches in thickness.

The ironstones worked at Comrie, Oakley, Inzievar, Cowdenbeath, and Lumphinnans in Fifeshire—Kinneil, Grange, and Balbardie in Linlithgowshire—Croy, Banton, Kilsyth, and Kirkintilloch in Dumbartonshire—Dolphingstone, Tranent, and Wallyford in East Lothian—Dryden in Mid Lothian—Johnstone and Paisley in Renfrewshire—Muirkirk and Dalry in Ayrshire—Possil, Garscadden, Kenmure, and Cadder in Lanarkshire—correspond in position with the ironstones lying under the Possil or Cowglen limestone.

Between the Dalry blackband ironstone and the Hurlet coal there are numerous clayband ironstones; but with the exception of one or two which have been partially worked at Hurlet there are none workable. In the position of the Hurlet coal itself there is sometimes found a band of ironstone, as at Easterhouse near Carnwath; but it is usually so contaminated with sulphur as to be quite unsuitable for ironmaking purposes.

Fitting and Working of Collieries.—The depth at which the seams of coal and ironstone are usually found varies from 20 to about

400 yards. The pits in the neighbourhood of Glasgow reach the Splint coal at from 140 to 180 yards, and at Baillieston it is reached at from 140 to 250 yards. At Wishaw the pits seldom exceed 120 or 140 yards to the Ell coal. The deepest pits sunk in the district are the Nitshill Victoria pit near Hurlet, sunk 350 yards to the Hurlet coal, about 5 miles south west from Glasgow; and the Snab pit at Kinneil, sunk 396 yards to the Eastermain coal. Some of the pits at Possil and the neighbourhood are sunk considerably more than 200 yards to the Possil ironstone.

The shape of the pits in plan is generally oblong, varying in size from 10 by 5 feet to 20 by 6 feet, according to the size of pumps to be put in the shafts. These shafts are usually divided into two compartments, a space of 4 or 5 feet at the rise end of the shaft being kept solely for the purpose of the upcast shaft, and the remaining distance divided for the pumping and winding arrangements. Fig. 3, Plate 74, is a plan showing the ordinary division of the shaft, the upcast shaft A at one end being 4 feet wide, and the pumping shaft B at the other end 5 feet wide, while the centre portion C, 9 feet wide, contains two sets of winding gear. The brattice or midwall is made of planks of red pine cut to the width of the pit, 9 inches deep and 3 inches thick, let into the wall on each side of the pit, and made air-tight by corner rackings of wood, cut out of timber about 6 inches square. The slides for the cages are of red pine, usually 5 inches square. The needles or buntings for securing the slides are usually cut to a section of about 9 inches by 3 inches, and are placed in the shaft about 9 feet apart.

There is not generally much water in the Scotch collieries. The usual size of the pumps varies from 8 inches to 16 inches diameter of the rising main; and when the latter size is not exceeded, the rods are usually worked by bell cranks driven by a horizontal engine with crank and flywheel. Of late years where the diameter of the pipes has exceeded 16 inches, direct-acting engines have been adopted, with the cylinder placed vertically over the pumping end of the pit. The usual length of the lifts or sets of pumps is from 90 to 100 yards.

Only two systems of working coal are employed in the district: that of "Stoop and Room," and the "Long Wall" working.

The Stoop and Room system, shown in Fig. 5, Plate 75, is much the same as that known in England as the "pillar and stall." As adopted in Scotland, it is customary to proceed with the working, leaving pillars or "stoops" D D containing about 55 or 60 per cent. of the coal for supporting the roof, until the pit has reached the limit of the area which has been laid out for working. The back working is then commenced, which consists in driving "rooms" through the stoops or pillars situated to the rise and on the level, as shown at E E, leaving only the four corners of the pillar. These corners are usually left 6 to 8 feet square, and are left in the pit permanently, and consequently are lost to the coal proprietor. The proportion of coal taken out of the field by this system varies from 70 to 85 per cent. of the total quantity of coal in the field. Seams of coal above 4 feet in thickness are usually worked by this method.

The Long Wall system is that usually adopted for working seams of coal under 4 feet in thickness and all seams of ironstone. This system is shown in Fig. 6, Plate 76, and by it the whole of the coal or ironstone is taken out of the pit. The working faces F F are carried forwards continuously from the shaft towards the rise and along the level on each side; and for the purpose of bringing away the coal as the working faces advance, packed roads G G are constructed through the goaf, by building up parallel walls of stone to support the roof, which are constantly carried forwards as the work advances.

The underground haulage is usually conducted by horses drawing on roads going along the level course of the seam. The rails employed are of cast iron, of an angle shape, about 4 inches deep in the side, cast in lengths of 4 feet, and weighing about 60 rails to the ton. The gauge to which they are laid is usually about 2 feet 10 inches, and each end of the rail is spiked to a larch sleeper, 6 inches broad by $2\frac{1}{2}$ inches thick, costing $1\frac{1}{2}d.$ to $2\frac{1}{2}d.$ each. The haulage of coals from dip workings is accomplished by means of stationary engines placed underground, and supplied with steam from boilers at the surface. The steam is carried down the upcast

end of the shaft in pipes, and the exhaust steam from the engine is conveyed about 20 feet up the shaft in pipes and then discharged to assist the ventilation. In some cases however the plan of letting the exhaust steam escape into the shaft has been found to injure the walls of the pit by loosening the strata; and in recent fittings it has been deemed advisable to convey the steam the whole distance up to the surface in pipes.

The dip and rise of the strata in the district varies from 1 in 10 to 1 in 3. When the inclination is so steep as 1 in 3, the minerals are lowered from the rise workings by self-acting inclines with a chain and a horizontal pulley at the head of the incline. The pulley is usually about 3 feet in diameter, and the chain for lowering the wagons is passed twice round the pulley to prevent slipping. The brake is applied to a friction ring cast on the side of the pulley.

The Scotch collieries cannot be said to be fiery: in few cases indeed are safety lamps required in working. Each pit has its fireman, who goes round the working faces of the pit each morning before the men proceed to work, to certify that all are free from fire. There are seldom any accumulations of gas except in places wholly shut off from the air current. In the "stoop and room" working, the stoops or pillars are almost invariably turned without the assistance of face brattices. The usual method of conducting the air current, as shown by the arrows in Figs. 5 and 6, is to split it at the pit bottom and lead it round the working faces, and back to the upcast end of the shaft by the heading drift H driven straight to the rise from the pit bottom. The size of the main airways is seldom larger than 20 square feet area, and the quantity of air travelling in each of the two splits does not often exceed 10,000 cubic feet per minute, or 20,000 cubic feet per minute total quantity of air passing through the entire mine.

The furnace is the universal rarefying power for ventilation. The steam jet as a principle has not been adopted, the only applications of steam for ventilating purposes being in working with underground engines, where the exhaust steam is discharged into the upcast shaft. The furnaces employed for ventilation are

built a good deal after the Newcastle model ; not so large certainly, but the same in shape. A section of a ventilating furnace is shown in Fig. 4, Plate 74 ; the firegrate K is about 7 feet long by 5 feet wide, placed about 20 inches or 2 feet above the floor. The spring of the arch is about 3 feet above the firebars, and the arch is turned with a rise of about $2\frac{1}{2}$ feet in the centre. The furnace is usually placed about 40 feet back from the upcast shaft, and the arch over the fire is built forwards into the shaft. The whole volume of the return air from the workings is made to pass over the firegrate, as the return current is never inflammable, and there is never any necessity for dumb drifts.

The usual form of winding engines employed is a pair of coupled horizontal engines with cylinders varying from 20 inches to 30 inches diameter, 4 to 5 feet stroke, and 10 to 13 feet winding drums on the first motion. The weight of the hutch or wagon bringing the coal from the collier is about 4 cwts., and it contains about 10 cwts. of coal. Two hutches are usually raised at a time, so that the load on each rope is about 28 cwts., exclusive of the cage which weighs from 5 to 7 cwts. The quantity raised from each pit ranges from 50 to 350 tons per day. Hemp ropes are in most common use : where wire ropes are used, round wire ropes are becoming more common in deep pits. Flat wire ropes were a good deal used ; but there is an impression among Scotch engineers that they are not economical, and this is attributed to an unequal straining on the different plies forming the rope, and they have been abandoned in many collieries on this account.

The cost of sinking and fitting the pits of course depends entirely upon the depth and the quantity of water to be contended with. The nature of the strata in all parts of the coalfield is about the same, consisting of alternating beds of sandstone and shale. Taking the average quantity of water to be raised from a pit at 250 gallons per minute, which is considered a fair quantity in the district, the cost of fitting and sinking a pit is—

for a pit 120 yards deep about £3,000.			
„	160 yards	„	£5,000.
„	200 yards	„	£7,000.

These sums are exclusive of the cost of the working plant for properly working the colliery.

The cost of working the coal and putting it in wagons for delivery, including royalty and all charges, varies from 3s. to 4s. 6d. per ton of $22\frac{1}{2}$ cwts. The first of these rates represents nearly the cost of raising the Wishaw Ell coal, and the latter the cost for the thinner seams under the Splint coal. The cost of raising and calcining the ironstone ready for delivery, including royalty and all charges, varies from 10s. to 18s. per ton of $22\frac{1}{2}$ cwts. The general average cost of coal at the Coatbridge Iron Works, including lordship, cost of working, and railway charges, ranges from 5s. to 5s. 6d. per ton; and the cost of calcined ironstone from 13s. 6d. to 20s. per ton. Limestone is generally purchased from the limestone quarriers, and costs delivered at the works about 5s. 3d. per ton.

The average royalty paid to the landlord is about 8d. per ton on coal. The Wishaw Ell coal however has recently realised as much as 1s. 3d. per ton. The lordship on gas coal is one eighth of the hill price or the price at the pit mouth. On blackband ironstone the lordship is 2s. 6d. to 3s. 6d. per calcined ton of $22\frac{1}{2}$ cwts.; and on clayband ironstone 1s. to 1s. 3d. per calcined ton of $22\frac{1}{2}$ cwts. The lordship on limestone is about 4d. per ton.

Railway and Canal Accommodation.—The district is accommodated by the Caledonian, Edinburgh and Glasgow, Monkland, Scottish Central, and Glasgow and South Western Railways; and by the Monkland, Forth and Clyde, and Union Canals.

The Caledonian Railway lies over the most valuable part of the coalfield, and accommodates the most valuable coals in the upper series of minerals. On the line from Glasgow to Edinburgh it passes the Caulm limestone and fireclay field at Garnkirk. It enters upon the coalfield at Gartcosh station, running over the outcrop of the Kiltongue coal. It then passes the collieries of Gartsherrie, Coatbridge, Whifflet, Holytown, and enters upon the great Wishaw coalfield at Motherwell and leaves it near Carluke. The Lesmahagow branch brings the gas coal from Lesmahagow, the ironstone from Bankend, and the upper coals from Larkhall,

Allanton, Ferniegair, and other collieries as far up the line as to near Auchenheath. The Wilsontown branch takes the gas coal and ironstone from Wilsontown and Forth. The Clydesdale Junction branch accommodates the Newton and Rutherglen coalfields, and serves as a route for the conveyance of coal from the Wishaw field to the south and east districts of Glasgow. The coal traffic on this line finds a shipping port at Glasgow, Greenock, Granton, and Leith on one system of railways; and at Kirkintilloch on board canal boats by means of the Kirkintilloch branch of the Monkland Railways.

The Edinburgh and Glasgow Railway main line passes over the Possil and Bishopbriggs ironstone field, and with the assistance of the Scottish Central and Monkland Railways opens up a communication between the Coatbridge ironworks and the Denny ironstone field. The Redding collieries are on the main line, and the Blackbraes collieries are connected with it by the Blackbraes branch. The Milngavie and Helensburgh branches pass over the Milngavie and Kelvinside mineral field. The only shipping port of the Edinburgh and Glasgow line on its own system is Grangemouth, but it is in communication with Leith and Granton by the Caledonian Railway.

The Monkland Railway system accommodates nearly the whole area containing the accessible portion of the slaty bands of ironstone, and conveys all the ironstones arising on it to the ironworks over one system of railway. It accommodates the Bathgate coal and ironstone field, and the coalfields of Slamannan and Airdrie. The shipping ports on the canal are Causeway End and Kirkintilloch, and Boness on the sea board.

The ironstone fields of Govan, Paisley, and Johnstone are accommodated by the main line of the Glasgow and South Western Railway.

The Monkland Canal conveys the coals in the Baillieston and Drumpeller districts to the ironworks or to Glasgow, or to Greenock by the Forth and Clyde Canal. The Union Canal conveys the coals from Redding and Causeway End to Edinburgh.

In conclusion it may be stated generally that the area containing the most valuable coals, which are those above and including the Splint coal seam, is comprised within the area shaded dark on the general plan, Fig. 1, Plate 72: it is bounded on the west by Glasgow; on the north by Greenfield, Cardowan, Easterhouse, Heatheryknowe, Gartsherrie, Airdrie, and Standrig; on the east by Clarkston, Chapelhall, and Cleland; and on the south by Dalserf and Larkhall. The area containing the Virtue Well, Kiltongue, and Drumgray coals, and the ironstones in their locality, extends as far north as Jawcraig, Falkirk, and Grangemouth; east as far as Bathgate; and south to near Carluke. The area containing the seams in the locality of the Possil, Garscadden, and Dalry ironstones extends as far north as Duntocher, Milngavie, Kilsyth, and Denny; and as far east as Bathgate and Wilsontown; and nearly as far south as Lanark. It has been from these districts that the supply of coal and ironstone has been almost wholly derived during the last hundred years.

The whole Glasgow mineral district, forming the subject of the present paper, contains 111 blast furnaces producing about 900,000 tons of pig iron per annum, and consuming about

2,500,000 tons of coal

1,485,000 tons of ironstone

445,000 tons of limestone.

The entire district contains about 260 collieries, which raise annually about 8,500,000 tons of coal, or nearly 77 per cent. of the whole produce of Scotland.

Mr. NEIL ROBSON thought the paper just read gave a clear account of the present state of the Glasgow coalfield, and he could confirm the accuracy of the statements contained in the paper. He enquired whether any attempts had been made to introduce coal-cutting machines practically in any part of this district, as he thought an application of machinery for that purpose was now

greatly needed for enabling the coal masters to keep their men in order. He had seen a coal-cutting machine at work at Hetton Colliery, Durham, about a year ago, which he thought highly of as a step in the right direction, though it would require a great deal to be done to it in order to make it practically useful. That machine had been obtained from Leeds by Mr. Nicholas Wood, for the purpose of showing it in operation at the Hetton Colliery during the meeting of the British Association at Newcastle. It was driven by compressed air, which was conveyed down the pit and then carried to the working face of the coal at a distance of 500 yards from the bottom of the shaft. He believed these machines were already increasing in number, but he was not aware of any of them having been put to work yet in the neighbourhood of Glasgow.

Mr. W. MOORE believed the only trial yet made in Scotland of a coal-cutting machine had been at a colliery at Redding, near Falkirk. The machine was worked by compressed air, conveyed down the pit in pipes of 3 or 4 inches diameter, and led a quarter of a mile underground to the machine.

Mr. RALPH MOORE said he had witnessed the experiments with two different coal-cutting machines at the West Ardsley Colliery near Wakefield and at Redding Colliery near Falkirk, but in neither case did the results lead him to think that the machine would become practicable for some time to come. The West Ardsley machine was simply an ordinary pick worked through a bell-crank lever by the piston rod of the air cylinder, giving a motion corresponding to the ordinary horizontal stroke of the pick in hand work: this did not seem to work very well at present, though it appeared likely to be made to answer ultimately. The trial at Redding had been made with a rotary motion of two picks, something like a circular saw with only two teeth, which had appeared to be a better plan: as yet however the machine had not been found fully successful, and it had consequently been abandoned at Redding for the present.

Mr. E. A. COWPER said that the coal-cutting machine working at the West Ardsley Colliery was that of Messrs. Donisthorpe Firth and Ridley of Leeds, and was working regularly at that colliery.

The action was simply that of an ordinary pick, worked backwards and forwards by means of a bell-crank lever, producing the same stroke that a man would give by hand, but with the advantage of greater force and regularity in the blows of the machine. The pressure of the compressed air was 40 lbs. per square inch, and the machine was worked by a boy moving the slide valve of the air cylinder by a handle for each stroke of the pick, in the same manner as in working a steam hammer. From the accounts that he had heard of the machine it appeared to be a thoroughly practical one, and performed the work of undercutting the coal, which was ordinarily done by the colliers lying on their backs. Mr. Nicholas Wood had expressed a very favourable opinion of the machine, stating that in hard coal it undercut about 50 feet length in the course of a night, and in softer coal about 100 feet; and the coal so undercut was then got by the colliers in the day.

The PRESIDENT enquired what length of coal a collier could ordinarily undercut in an hour, and what was the size of the excavation made in undercutting to a depth of 3 feet in from the face.

Mr. RALPH MOORE replied that a collier could undercut about 2 feet length of coal in an hour, and in undercutting to a depth of 3 feet the width of the cut would be about 6 inches at the face, tapering to a point at the further end. The motion of the pick in the West Ardsley coal-cutting machine was not exactly like that given by the collier by hand, as the machine merely struck the blow with the pick by a reciprocating movement, but a collier after striking the blow used the pick as a wrench to break the coal away; and until that wrenching motion also was obtained in working the pick by the machine, he did not think it would succeed very well. The circular saw motion that had been tried at Redding had been attempted as an improvement upon the simple pick, and the machine at Redding undercut a length of about 3 or 4 yards per hour to a depth of 3 feet in. That was the greatest amount of work it had accomplished in the hard coal at Redding; but the machine at West Ardsley had done considerably more, because it was working in very much softer coal.

Mr. NEIL ROBSON remarked that the machine which he had seen at work at the Hetton Colliery gave a great saving in coal as well as in collier's labour; since instead of taking out a cut 6 or 9 inches wide, as in hand cutting, it made a cut only about $2\frac{1}{2}$ inches wide on an average, and thus saved the rest of the coal that would have been excavated in hand labour, as the coal cut out was all made into dross or slack by the process of cutting. This did not matter so much in the case of the Newcastle coal, as that was a caking coal, and therefore the small coal was valuable and could be used for making coke; but with other coals the small coal was not of so much use, and was in fact partly wasted. The saving effected by the machine in cutting the coal was therefore great in respect of coal as well as in labour. He accordingly hoped to see coal-cutting machines brought into more general use.

Mr. J. MAXING had seen a hydraulic coal-cutting machine at work at the Kippax Colliery near Leeds, constructed by Messrs. Carrett and Marshall, having a horizontal arm projecting from the piston rod at the side of the machine and carrying a cutting tool or chisel, which was worked by water pressure with an action like a horizontal slotting machine; so that as the machine travelled along the face of the coal, the tool cut out a narrow notch or slot to the required depth. It thus saved the large amount of waste that was occasioned by the quantity of small coal necessarily made in under-cutting by hand labour.

Mr. W. P. BEALE enquired whether there was found to be any danger of spontaneous ignition of the coal in the Scotch collieries in working on the long wall system, where it was necessary to keep roads open through the goaf; and what precautions were adopted to guard against such an occurrence. He asked also whether any case was known in which ignition had been the result of the exposure of pyrites to the air in the pit, or whether there was any other cause of danger.

Mr. W. MOORE believed the only coal in Scotland liable to spontaneous ignition was the Hurlet coal, the lowest in the coal-field. It took fire a few years ago in the Victoria Pit West, near Nitshill, but the fire was very slight, and was soon put out.

In that case the ignition was attributed to pyrites, nor did he know of any other cause. Spontaneous ignition however was not by any means of frequent occurrence, and that was the only instance of it that he knew of during the past seven or eight years.

Mr. RALPH MOORE said that in collieries where there was any liability to spontaneous ignition of the coal, in working on the long wall system, the practice was to build a double wall on each side of the roads through the goaf, the centre of each wall being filled in like a cofferdam with about 6 or 8 inches thickness of sand. Then when the roof came down it compressed the sand and made the walls perfectly air-tight, preventing any air from getting through into the goaf. He had had occasion recently to examine some workings where the roads had been constructed in that way through the goaf, and at one place he had had a hole broken into the wall at a distance of about 30 yards behind the point to which the workings of the coal had then advanced, in order to see the state of the wall after standing that length of time; and he found the layer of sand inside the wall was quite solid, forming an effectual barrier to the passage of air.

The PRESIDENT enquired what was the relative durability of the hemp and wire ropes used for winding in the pits, and whether any steel wire ropes were used for the purpose in the Scotch collieries; also what diameter of pulley was generally used for them to work over.

Mr. W. MOORE had found that a hemp rope used for winding in a pit 200 yards deep lasted about 15 months with ordinary working, drawing from 150 to 200 tons per day; and a round iron wire rope under the same work lasted 12 or 13 months, while a flat wire rope lasted only about 11 months. The pulleys employed over which the rope passed were generally 10 to 12 feet diameter. He did not know of any steel wire ropes being used at any of the collieries in that district.

Mr. D. ADAMSON believed steel wire ropes were now being adopted for winding at several collieries in England, and had no doubt their application for that purpose would be very valuable, as he understood the practical success of steam ploughing had been

attributed by Mr. Fowler in a great measure to the introduction of steel wire ropes in place of iron wire, on account of the superior strength and lightness of the steel ropes. The results of working with steel wire ropes as compared with hemp ropes for colliery winding had been found to be that, when a flat wire rope passed over the winding drum and the pulley with both bends in the same direction, the steel rope lasted longer than the hemp rope of the same original tensile strength; but in winding with two ropes, the second rope must pass over the pulley and under the winding drum, and was thus bent in opposite directions; and in that case a steel rope was found not to last half as long as when both the bends were in the same direction.

The PRESIDENT moved a vote of thanks to Mr. Moore for his paper, which was passed.

The following paper, communicated through Mr. Daniel Adamson of Manchester, was then read:—

ON THE CONSTRUCTION OF BLAST FURNACES AND THE MANUFACTURE OF PIG IRON IN THE CLEVELAND DISTRICT.

By MR. JAMES GEORGE BECKTON, OF WHITBY.

Within the last ten years the Blast Furnaces which have been erected in the Cleveland district have been gradually increased in size both in diameter and height; and these alterations have thus far been attended with good results, so much so that almost all the new furnaces now in course of erection are being built with boshes ranging from 16 feet to $22\frac{1}{2}$ feet diameter, and from 60 feet to 75 feet in height from the bottom of the hearth to the filling plates at the top. Previously the furnaces ranged from 13 feet to 15 feet diameter at the boshes and from 45 feet to 50 feet in height, the extreme increase being about 70 per cent. in both dimensions. The maximum diameter of the boshes appears not yet to have been attained; and the limit to the height will apparently be found in the strength of the coke to support the crushing force of the high column of materials in the large blast furnace. The make of pig iron has increased at the same time from 200 tons per week in the small furnaces to 300 tons in the large furnaces.

The average quantity of materials used in the production of one ton of pig iron in the large furnaces is as follows:—

26 cwts. of Durham coke,
70 cwts. of Cleveland ironstone,
15 cwts. of limestone,
10 cwts. of coal for boilers, hot-blast stoves, and calcining kilns.
<u>121</u> cwts. total

or about 6 tons of materials per ton of iron made. Formerly the quantity of coke used per ton of iron made averaged 35 cwts. instead of 26 cwts., and the quantity of coal 20 cwts. instead of 10 cwts. The writer does not attribute the whole of the saving of

fuel which has taken place to the increased size of the furnaces alone, as there are several other improvements which have combined to produce an economy of fuel in the manufacture of pig iron in the Cleveland district, of which the following are some of the principal :—

First, the more efficient management which has taken place at the different works.

Second, the better adaptation of engine power and hot-blast stoves to the requirements of the furnaces.

Third, the improved system of calcining the ore, which was formerly carried on by clamping in the open air, but is now performed in properly constructed calcining kilns.

Fourth, the higher degree of temperature of the blast supplied to the furnaces, which was formerly heated in the hot-blast stoves to only 600° or 700° Fahr., but is now very generally being supplied to the furnaces at a temperature of from 800° to 900°.

Fifth, the plan of taking off the waste gas from the furnaces and burning it at the boilers and hot-blast stoves, in place of using additional coal for this purpose.

The application of the waste gas to the boilers and hot-blast stoves is becoming very general at the different works in the district; and arrangements are now being made at several of the new works in course of erection for applying it to the calcining kilns, for the purpose of calcining the ironstone. The plan in general use for taking off the gas from the blast furnace is the closed furnace top with bell and hopper sufficiently large to charge from 8 to 10 tons of materials into the furnace at once, and with an arrangement for raising and lowering the bell by hand. The impression seems to be gaining ground that taking off the gas with the closed top, and in connection with a large chimney double the height of the furnaces, does not interfere with the operations of the large furnace, either as regards economy of fuel or quality and make of iron.

A noticeable feature in the large furnaces is the greater amount of time the materials are allowed to remain in the furnace. The capacity of the Thornaby furnaces, shown in section in Fig. 4,

Plate 80, with 20 feet boshes and 60 feet height, is 12,361 cubic feet; the area of the boshes is 314 square feet, and the make of iron 300 tons weekly per furnace. The capacity of the small furnaces which were formerly erected, with 14 feet boshes and 50 feet height, is 5553 cubic feet; the area of the boshes is 154 square feet, and the make of iron 200 tons weekly per furnace. In the large furnace therefore there are more than twice the quantity of materials undergoing the process of heating, and also remaining a longer time in the furnace. Moreover the area of the boshes in the large furnace being double that in the small furnace, while the quantity of iron produced by the large furnace and consequently the quantity of blast supplied is only one and a half times as much as in the small furnace, it follows that the ascending gases pass through the materials at a slower velocity and at a lower temperature in the large furnace. This allows the coke to descend to the zone of fusion without losing so much of its carbon in the formation of carbonic oxide as previously in the small furnace; and hence arises the greater economy of fuel in the large furnace. To produce 300 tons of pig iron per week, the large furnace requires to be supplied with 8000 cubic feet of blast per minute at a pressure of 3 lbs. per square inch.

Fig. 1, Plate 77, is a vertical section of one of four furnaces at the Ormesby Iron Works, Middlesbrough, belonging to Messrs. Cochrane. These furnaces were erected in 1855, and were the largest in the district at that time; the boshes are 16 feet diameter and the height is $56\frac{1}{2}$ feet. The furnaces are constructed upon land consisting of mud and silt, and piling had therefore to be resorted to in order to secure a good foundation for the furnaces. A bed of concrete was placed on the top of the piles, and six inverted arches were turned on the top of the concrete, and the brick pillars carried up, and strong cast iron bearers fixed across the top for carrying and binding the brickwork of the barrel and boshes. The outer shell is bound with wrought iron hoops, fixed near enough together to prevent the barrel from cracking. The boshes are at an angle of 75° from the horizontal.

Fig. 2, Plate 78, is a vertical section of one of four furnaces erected in 1858 at the Jarrow Iron Works, Newcastle-on-Tyne. There was a good strong clay for the foundations of the furnaces to rest upon; the brickwork was carried up to the floor line, then twelve cast iron columns were erected, and wrought iron casings fixed on the top of these. The casings extend from the top of the five tuyere houses to the top of the boshes, above which the barrel is bound with wrought iron hoops supported by **T** irons, the latter being carried up to the top, and a flat ring rivetted to them sufficiently strong to carry the floor plates. The boshes are 18 feet diameter, at an angle of 66° from the horizontal, and the furnaces are 60 feet high.

Fig. 3, Plate 79, is a vertical section of one of three furnaces at the Normanby Iron Works, Middlesbrough, belonging to Messrs. Jones, Dunning and Co. These furnaces were erected in 1860, and are constructed upon a bed of concrete, on clay of a weak nature; they are supported on brick pillars and hooped similarly to the Ormesby furnaces. The boshes are 18 feet diameter, at an angle of 72° from the horizontal, and the furnaces are 58 feet high.

Fig. 4, Plate 80, is a vertical section of one of three furnaces erected in 1862 at the Thornaby Iron Works, South Stockton-on-Tees, belonging to Messrs. Whitwell. These furnaces are constructed upon piles, in consequence of the land being mud and silt; they stand each upon twelve cast iron columns, and are cased with iron similarly to the Jarrow furnaces. The boshes are 20 feet diameter, at an angle of 68° from the horizontal, and the furnaces are 60 feet high.

Fig. 5, Plate 81, is a vertical section of one of three furnaces which are being erected at the Acklam Iron Works, Middlesbrough, by Messrs. Stevenson, Wilson, Jaques and Co. They are being built on piles, in consequence of the land being mud and silt, and are each supported by twelve cast iron pillars. The brickwork around the boshes is cased with plates, and from the boshes up to the top the barrel is bound with hoops and **T** irons. The boshes are $22\frac{1}{2}$ feet diameter, at an angle of 68° from the horizontal, and the furnaces are 70 feet high. These furnaces the writer believes

to be the largest in dimensions that have ever been erected, and their contents will amount to no less than 1250 tons of materials per furnace: they are expected to produce each 350 tons of pig iron per week.

Mr. D. ADAMSON regretted that Mr. Beckton was unexpectedly prevented from being present at the meeting. With some of the blast furnaces in the Cleveland district he had himself had an opportunity of becoming acquainted; and in reference to the semiclosed plan of furnace top, for taking off a portion of the gas from the furnace throat, as shown in the drawing of the Thornaby furnace, Fig. 4, the construction of top in this case was similar to that in use at Messrs. Schneider's furnaces near Ulverstone; but although at the Ulverstone furnaces it had been found to work so successfully that the same plan was being adopted for more furnaces at the same works, in the particular instance of the Thornaby furnaces it had not been found to answer. The centre tube or brick chimney for taking off the gas was carried upon six arches springing from the inside of the furnace throat, and the charging of the materials into the furnace was done through the spaces left between the arches; and the reason of the failure of the plan at the Thornaby furnaces was that constant trouble was occasioned by the damage done to these arches in charging, owing to the large size of the material in the charges. The Cleveland ironstone was raised from the mines and supplied to the furnaces in very large pieces, and would not pay for being broken to a smaller size, on account of its friable nature and the quantity of waste that would be made in breaking it up; and in charging the furnace with these large pieces they broke down the arches carrying the centre tube, so that this plan had now been abandoned at the Thornaby furnaces, and they were about to have closed tops put on of the usual construction for taking off the whole of the gas.

Independent however of the trouble arising with the arches in the semiclosed plan of furnace top, it was also found at the Thornaby furnaces that the portion of the gas so taken off was not sufficient in quantity for the purposes of raising steam at the works and heating the blast, even without attempting to use any of the gas for calcining the ironstone. In the discussion of this subject at the Liverpool meeting in last year he had urged the desirability of taking off the whole of the gas from a furnace, on account of the large additional heating power then at command; and this view appeared to be confirmed by the experience in the present instance at Thornaby, and by the statement given in the paper just read that at some of the Cleveland furnaces where the top was entirely closed the gas was likely to be employed for calcining the ironstone in addition to heating the steam boilers and the hot-blast stoves.

The PRESIDENT enquired what was the effect of the increased size of the Cleveland blast furnaces upon the quality of the iron made.

Mr. D. ADAMSON understood that in the larger furnaces foundry iron was made with rather less trouble than in the smaller ones; and with considerably less fuel, according to the statement in the paper. The charge was thus lighter and the iron was made at less cost in the larger furnaces, which was attributed in the paper to the greater length of time that the materials remained in the larger furnaces.

The PRESIDENT asked what size of blowing engine was used for the large furnace at the Acklam Iron Works.

Mr. D. ADAMSON was not aware what size of engine was used at the Acklam furnaces, but the majority of the Cleveland furnaces were supplied with blast by a number of small blowing engines, and the rest by a single large engine. With regard to the pressure of the blast, he believed 3lbs. per square inch or rather less was usually about the pressure at the engine in the Cleveland district, but he doubted whether the full pressure of the blast was always obtained in the furnaces, as it had been found by applying gauges on the tuyeres at the Thornaby furnaces that the pressure at that point was considerably below what it was at the engine. At the Norton

furnaces of Messrs. Warners, near Stockton-on-Tees, the pressure originally employed of $2\frac{3}{4}$ lbs. per square inch had now been reduced to only $\frac{1}{2}$ lb. per square inch ; and he understood the lighter blast was preferred at those furnaces, and that a greater quantity of foundry iron was made than with a heavier pressure of blast.

The PRESIDENT enquired what was the usual number of tuyeres in the Cleveland furnaces.

Mr. D. ADAMSON replied that from three to six tuyeres were usually employed. At the Norton furnaces three large tuyeres were now used with the light blast, instead of six smaller tuyeres employed previously with the heavier blast ; and from the reduction in the pressure of the blast, much less engine power was now required in blowing the furnaces for the same make of iron. At another furnace however in the neighbourhood, the engines had been kept loaded to $2\frac{3}{4}$ lbs. per square inch pressure, while the pressure of the blast was reduced by throttling its passage through the main by means of a stop valve ; and in that instance consequently the full benefit of saving in engine power by working with a lighter blast had not been realised.

Mr. G. THOMSON observed that the size of the blast furnace was a very important subject to iron makers, and one upon which experience differed a good deal ; and it was therefore highly desirable to get all the information possible, in order to make a fair comparison between different sizes of furnace. One point to be enquired into was the relative quantity of iron produced and of blast supplied in the large and small furnaces : in the large furnaces, 60 feet high and 20 feet diameter of boshes, making 300 tons of iron per week, the quantity of blast had been stated in the paper to be 8000 cubic feet per minute ; and he enquired what was the quantity of blast supplied to the smaller furnaces, 50 feet high and 14 feet diameter of boshes, making 200 tons of iron per week.

Mr. NEIL ROBSON did not know the quantity of blast supplied in the smaller Cleveland furnaces, but in the blast furnaces of the Glasgow district the quantity of blast supplied to a furnace about 50 feet high and 16 feet diameter of boshes was usually supposed to be about 6000 cubic feet per minute.

Mr. C. COCHRANE thought the 8000 cubic feet of blast per minute, which had been stated to be the supply to the large Cleveland furnaces, must be the theoretical quantity measured by the total displacement at the blast engine, without any allowance being made for escape between the piston and the cylinder and for leakages in the blast main: for the quantity of coke consumed in the furnace, 26 cwt. per ton of iron made, would not require he thought more than 6000 to 6300 cubic feet of blast per minute, and he could not understand therefore so much as 8000 cubic feet per minute being supplied to the furnace.

Mr. G. THOMSON remarked that 6000 cubic feet of blast per minute would be a maximum quantity in Staffordshire, and there were many furnaces of smaller size in that district to which a much smaller quantity of blast was supplied.

Another point upon which further information was required in connection with the Cleveland blast furnaces was the temperature of the blast in the large and small furnaces, and whether the large furnaces had been worked with the lower temperature of blast used in the smaller ones. It appeared from the paper that the blast for the larger furnaces was heated to 800° Fahr., while in the smaller furnaces the temperature had not been carried beyond 600°; and in order that a fair comparison might be arrived at between the different sizes of furnace, he should be glad to know the result of working the larger furnaces at the lower temperature of 600°, the same as the small furnaces, since the conditions of working should be made as nearly as possible the same in the different furnaces. The actual temperature of the blast he believed was generally much higher than was indicated by the ordinary rough test of holding a strip of lead in the blast to be melted by the heat; since in order to melt the lead at all under such circumstances, the temperature of the blast must be considerably above the melting point of the metal, and the real temperature was therefore not ascertained with any approach to accuracy by the plan of melting metals in the blast. He enquired how the heat of the blast was ascertained when it was much above the melting point of lead, and whether any pyrometer was employed for showing the temperature accurately.

Mr. C. COCHRANE replied that for temperatures above that indicated by the melting of lead in the blast a strip of zinc was used as the test instead of lead, and by that means a temperature as high as about 850° was indicated, the melting point of zinc being 770° Fahr.; for the actual temperature of the blast, when hot enough to melt either lead or zinc, was found to be as much as 80° or 90° above the melting point of the metal. This was ascertained to be the case as a general rule, whatever the melting point of the metal employed, as was shown by the aid of the improved pyrometer constructed on the principle of measuring the temperature of a copper ball heated in the blast, by immersing it in a vessel of water; which afforded the means of measuring with the greatest accuracy the highest temperatures that were likely to be met with in practice.

Mr. E. A. COWPER explained that the pyrometer referred to was an improved arrangement of that invented by Mr. John Wilson and described at a former meeting of the Institution (see Proceedings Inst. M. E., 1852, page 53), and was a very simple and accurate contrivance for measuring high temperatures. It consisted of a copper vessel holding exactly a pint of water, and a small cylindrical piece of copper made of such a size that its total capacity for heat should be 1-50th that of the pint of water; this copper piece was held for a sufficient time in the current of heated blast until it had acquired the full temperature of the blast, and it was then dropped into the vessel of water, when each 50° that the temperature of the copper had been raised produced a rise of 1° in the temperature of the water; and thus the real temperature was at once read off from a thermometer inserted into the water, having a properly divided scale showing 50° for each 1° of the ordinary scale (see Proceedings Inst. M. E., 1860, page 59). It was by this means that it had been ascertained that, when the heat of the blast was tested by a stick of metal being just melted on exposure to the current, the actual heat of the blast was about 70° to 90° Fahr. above the melting point of the metal. Thus if lead, melting at 620° , were just melted by the blast, the heat of the blast might be taken to be about 690° ; zinc melted at 770° and would show about

840°; and antimony did not melt at less than 830°, and its melting would therefore indicate about 900°. Of course if the stick of metal were melted quickly in the blast, it showed that the temperature was much higher than the melting point of the metal; and ordinarily the sticks of antimony of about 5-16ths inch diameter became fused in 3 or 4 seconds by exposure to the heated blast from the regenerative hot-blast stoves.

Mr. NEIL ROBSON observed there could be no doubt as to the importance of the question of the height of blast furnaces; and it appeared from the paper a height of 70 feet had now been reached in the Cleveland district, while in the neighbourhood of Glasgow the highest furnace was only 55 feet, and generally the furnaces were not more than 42 feet high. At the Ardeer Iron Works in Ayrshire, where there were four furnaces, each 52 feet high and 16 feet diameter at the boshes, the regular make of iron was 1000 tons per week, or an average of 250 tons per week from each furnace: occasionally one or two of the furnaces would make 270 tons per week, while the others might make less than 250 tons at the same time; but 1000 tons per week was the regular average make throughout the year taking all four together. The highest make in the Cleveland district was stated at about 300 tons per week, with 60 feet height and 20 feet diameter of boshes; but in comparison with the Scotch furnaces the make of the larger Cleveland furnaces ought to be as much as 400 tons per week for the size of furnace used. The temperature of blast employed was in both cases from 800° to 900°, and the pressure about 3 lbs. per square inch. Hence he thought the cause of the smaller produce of the large Cleveland furnaces was to be sought in the materials that had to be worked, the nature of the ironstone to be smelted and the quality of the fuel to be used. In the Ardeer furnaces the ore employed was in a great measure the blackband ironstone, and the fuel was raw coal; and he presumed these must be easier smelted than the materials in the Cleveland district, since the Scotch furnaces, though so much smaller, produced nearly as much iron in the same time.

The PRESIDENT enquired whether the furnaces 55 feet high and 16 feet diameter at the boshes were the largest furnaces in the Glasgow district.

Mr. NEIL ROBSON replied that those were the largest of the Scotch furnaces. The increase of height now taking place in the Cleveland district he considered was a step altogether in the right direction, and he thought the proper height of furnace had probably not yet been attained in Scotland.

Mr. F. J. BRAMWELL enquired what was the amount of the different materials employed in the Scotch furnaces of 52 feet height and 16 feet diameter, to produce a ton of iron ; because the production of a furnace must of course depend upon the total quantity of the materials that had to pass through it for each ton of iron made. It appeared from the paper that in the Cleveland district about $5\frac{1}{2}$ tons of material went into the furnace per ton of iron made ; and as the Scotch blackband ironstone calcined was a far richer material than the Cleveland ironstone calcined, it would be expected that less material would be found to be required per ton of iron in the Scotch furnaces than in the Cleveland furnaces, and thus the production of the latter would be less in proportion to their capacity than that of the Scotch furnaces.

Mr. NEIL ROBSON considered the quantity of materials required in the furnace per ton of iron made must certainly depend upon the nature of the ironstone used ; and in the Scotch furnaces that he had referred to the ironstone employed was about two thirds blackband and one third clayband and hæmatite ore. With these ironstones the quantities of materials required to make a ton of pig iron were about 38 cwts. of ironstone, 36 cwts. of raw coal, 6 cwts. of limestone, and 10 cwts. of coal for the boilers, hot-blast stoves, and calcining : making a total of 4 tons 10 cwts. of materials required per ton of iron made, or about 4 tons passing through the blast furnace to yield 1 ton of iron, as compared with the $5\frac{1}{2}$ tons stated to be required in the Cleveland district to produce the same quantity.

Mr. D. ADAMSON observed that the difference was still more marked in the case of furnaces working with the hæmatite ironstone, where the quantity of ironstone required per ton of iron made was about 35 cwts., with 5 cwts. of limestone and 20 cwts. of coke, making a total of only about 60 cwts. or 3 tons of materials passing

through the furnace to make a ton of iron. At Messrs. Schneider's furnaces at Ulverstone, in consequence of this advantage in working the hæmatite ore, he understood the regular make of each furnace was not less than 400 tons of pig iron per week, which could be increased to 600 tons per week by heavy working; and in one instance, by way of trying what could be done, a production of as much as 700 tons in a week had been obtained from one furnace. A mere glance at the works was sufficient to show the great difference in the ores worked in the two districts, by the comparative absence of slag at the furnaces working the hæmatite ore, and the very large quantity of slag produced from the Cleveland furnaces, which indicated the larger quantity of material that had to be operated upon in the latter case to produce a ton of pig iron. In one district the process was comparatively cleanly, while in the other it was dirty and rough, leaving a great deal of refuse.

Mr. F. J. BRAMWELL enquired what was the length of time that the charge took to pass through the furnaces of the different sizes described in the paper.

Mr. C. COCHRANE said that in the Ormesby furnaces of $56\frac{1}{2}$ feet height and 16 feet diameter, 36 hours was reckoned as the time that the charge remained in the furnace; that is from the time the material was put into the furnace till it was converted into iron in the hearth 36 hours was all that was necessary. This was ascertained by observing that when any alteration was made in the charging of the materials at the furnace top, it took about 36 hours before the corresponding change took place in the iron produced in the hearth. The time the material remained in different sizes of furnaces was in direct proportion to the capacity of the furnace or the quantity of material contained in it, provided the volume of the blast supplied to the furnace remained the same.

Mr. F. J. BRAMWELL observed that if that were the case, the length of time that the materials remained in the large furnaces would probably be as much as three days; and he enquired whether it was likely they were actually so long in passing through the furnace.

Mr. C. COCHRANE explained that, if the volume of blast supplied to the larger furnaces were no more than what was blown into the

smaller furnaces in which the materials remained about 36 hours, the time in the larger furnaces of 70 feet height and $22\frac{1}{2}$ feet diameter would no doubt be as much as 72 hours, owing to the capacity of the furnace and quantity of material being double as large. The length of time however was not a question solely of the quantity of materials in the furnace, but also of the volume of blast supplied; and the larger furnace would stand a very much heavier volume of blast without working less economically. In practice the increased quantity of blast supplied to the larger furnace was probably such as to reduce the time of the material being in the furnace to about 40 hours; but he was not aware what was actually the state of the case in that respect. He did not think there was any advantage to be gained by unnecessarily detaining the materials in the furnace; and as 36 hours was found sufficient for their passage through the smaller furnaces in the Cleveland district, there appeared no object in endeavouring to make them take longer in passing through the larger furnaces.

Mr. G. THOMSON thought it was still a question for consideration whether the proper length of time for keeping the materials in the blast furnace had yet been arrived at, and whether this ought to be longer in the larger furnaces than in smaller ones. Of course if the time was to be the same in both, the larger furnaces would require a very much increased volume of blast, so as to make the larger quantity of materials pass through with sufficient rapidity. The actual length of time that the materials took to pass through the large furnace might be deduced, he thought, from the capacity of the furnace and its weekly make, if the time of 36 hours in the smaller furnace were adopted as a criterion. For if 36 hours were the time in a furnace of 5000 cubic feet capacity, producing 200 tons of iron per week, it would follow that in a furnace of 12000 cubic feet capacity, working with the same materials and producing 300 tons of iron per week, the materials would occupy $36 \times \frac{12000}{5000} \times \frac{200}{300}$ or about 57 hours in passing through the furnace. The length of time must however depend upon the nature of the materials employed in different districts, which would determine the volume of blast that could be supplied to the furnace.

It was not the size of a furnace alone however that affected its make, but the shape of the furnace had also much to do with the result : and the shapes shown in the sections of the three furnaces at Ormesby, Jarrow, and Normanby were so different, that it would be highly desirable to ascertain what were the differences in the results of working of these furnaces with the same materials.

The PRESIDENT enquired what had been the reasons why the plan of taking off the waste gas from the blast furnace had not been carried out at the Scotch furnaces, as he was not aware of the gas being taken off from any furnaces in Scotland, though so much had been done in that respect in other places.

Mr. NEIL ROBSON replied that taking off the waste gas from the furnace head, and applying it to heat the boilers and hot-blast stoves and to calcine the ironstone, had never been successfully accomplished hitherto in any of the Scotch ironworks : it had been tried ten or twelve years ago at several ironworks in Lanarkshire, but there had been several bad explosions of the gas which had done great damage, and these, combined with the belief that the closed top had a prejudicial effect on the working of the furnace, led to the abandonment of the attempt. He did not see however why it should not yet prove successful, and was glad to learn it was now succeeding in the Middlesbrough district. Perhaps some explanation of the failure in the Scotch furnaces might be found in the use of raw coal in those furnaces, which produced more gas than the coke burnt in the Cleveland furnaces.

Mr. C. COCHRANE thought the explosions that had occurred in taking off the waste gas could only have arisen from a want of proper precautions. At the Ormesby furnaces they had had one or two severe explosions in starting the process, from the men not being quite up to it, and allowing the air to get back into the gas main, and not igniting the gas at the proper time. The danger was that, if the gas was not ignited at the point intended, it accumulated in the chamber where it ought to be burning ; and a light applied then was necessarily followed by instant explosion. It was only necessary however to keep the gas constantly ignited at the proper point, and to take care that the unignited gas was never allowed

to reach a chamber where it could become mixed with air and afterwards be ignited. The use of raw coal in the blast furnace instead of coke would not at all increase the danger of explosion; the only difference would be that a richer and more valuable gas would be given off from the furnace burning coal, and when taken off such a gas would develop a greater amount of heat for the purposes to which it was applied.

The PRESIDENT remarked that there was all the more reason on that account why the waste gas should be utilised from the Scotch blast furnaces, and it was satisfactory to learn that there were no practical obstacles to the plan which might not be successfully overcome. He enquired whether there was any mechanical means of preventing the air from ever passing back into the unignited gas, or whether it depended upon the care of the workmen in keeping the gas constantly ignited.

Mr. C. COCHRANE replied that it was necessary to keep a small fire always burning in any chamber where the gas was to be lighted, in order to ensure maintaining such a temperature that the gas should always become ignited at the moment of entering the chamber.

Mr. G. ADDENBROOKE thought the reason why the waste gas had not been more extensively taken off from blast furnaces was the want of a sufficiently powerful chimney draught to draw off the gas when the furnace top was left partly open. With an entirely closed top there was indeed the pressure of the blast in the furnace, to follow up the gas and aid in expelling it from the top of the furnace; but many descriptions of coal were not fitted to stand the increased pressure of blast that was rendered necessary to a certain extent with a closed top in order to overcome the consequent back pressure in the furnace; and the partly open top adopted for taking off the gas in such cases required the suction power of a large chimney for drawing the gas down from the furnace top.

Mr. F. J. BRAMWELL observed that at Messrs. Schneider's works an exhausting fan had been adopted to aid the chimney in drawing down the gas from the partly open furnace top; and he considered the use of a fan was decidedly the right way to draw off the gas,

and thought the gas should also be washed in order to free it from dust before it was made use of for heating purposes.

Mr. T. J. PERRY understood the exhausting fan that had been tried at Messrs. Schneider's works had been discontinued there, and that it had been found that a tall chimney of great capacity was practically more efficient for drawing off the waste gas from the blast furnaces.

The PRESIDENT enquired whether the exhausting fan was not employed at some of the French ironworks for drawing off the gas from the blast furnaces.

Mr. F. J. BRAMWELL believed that was the case, and that the plan of washing the gas after drawing it off had also been carried out there.

Mr. E. A. COWPER explained that the French plan that had been mentioned of washing the gas drawn off from blast furnaces, which was very effective, consisted in passing the gas through a very long horizontal pipe of D section, with the round side uppermost Ω , and the bottom open, except that it was sealed by water contained in a long shallow trough, considerably wider than the pipe, thus forming a long water joint, and affording the greatest facility for removing the dust from the bottom of the trough without any stoppage.

Mr. G. THOMSON thought there would be a deposit of tar in the gas from furnaces using raw coal alone, which might cause some trouble.

The PRESIDENT moved a vote of thanks to Mr. Beckton for his paper, which was passed.

The PRESIDENT proposed a vote of thanks, which was passed, to the Local Committee, the Chairman Mr. Walter M. Neilson, and the Honorary Local Secretary Mr. J. Wyllie Guild, for the excellent arrangements they had made for the meeting of the Institution in Glasgow; and also to the Lord Provost and the members of the City Council for their courtesy in accompanying the Members over the Water Works at Mugdock on the previous afternoon; and to the various Railway Companies for the facilities they had kindly afforded to the Members for attending the meeting in Glasgow and the Excursions in connection with the meeting.

A cordial vote of thanks was then passed to the President for his kind exertions in promoting the success of the meeting of the Institution in Glasgow, and the hearty welcome he had secured for the Members on the occasion.

The Meeting then terminated. In the afternoon the Members visited the Govan Iron Works, the Parkhead Forge, the Locomotive Works of the Edinburgh and Glasgow and the Caledonian Railways, and the Hyde Park Locomotive Works. A large number of engineering and shipbuilding establishments and other works were also opened to the inspection of the Members during the days of the meeting.

In the evening the Members and their friends dined together in the Queen's Rooms, in celebration of the meeting of the Institution in Glasgow.

On Thursday, 4th August, the Members visited Messrs. Napier's and Messrs. Tod and Macgregor's Ship Building Yards at Govan, and witnessed the operations of the Steam Dredgers upon the Clyde, being conveyed down the river by a special steamer. The Members afterwards proceeded up Gareloch, on the invitation of the President, to his residence at Shandon, where they were most hospitably received and entertained by the President; and in the evening they returned to Glasgow by the special steamer.

On Friday, 5th August, an Excursion was made by the Members from Glasgow to visit the works of the Loch Katrine Water Works at Loch Vennachar and Loch Katrine, passing through the Trosachs and returning by Loch Lomond, where they were handsomely entertained by the Local Committee.

PROCEEDINGS.

3 NOVEMBER, 1864.

The GENERAL MEETING of the Members was held in the Lecture Theatre of the Midland Institute, Birmingham, on Thursday, 3rd November, 1864; EDWARD A. COWPER, Esq., Vice-President, in the Chair.

The CHAIRMAN announced that the subject of the continued inefficient state of the Patent Office had been under the consideration of the Council, and the following Memorial to the Lord Chancellor had been prepared, and would lie for the signature of Members at the close of the Meeting.

(Copy of the Memorial.)

TO THE RIGHT HONOURABLE THE LORD WESTBURY,
LORD HIGH CHANCELLOR.

We, the undersigned, Officers and Members of the Institution of Mechanical Engineers, being interested in the due and efficient working of the Patent Law Amendment Act of 1852, beg most respectfully to call your Lordship's attention to the report presented to the House of Commons by its Select Committee, appointed on 9th May 1864, "to enquire as to the most suitable arrangements to be made respecting the Patent Office Library and Museum;" and to represent to your Lordship the great desirability that immediate steps should be taken for carrying out the conclusions arrived at by the Committee on the evidence, and embodied in their report: namely, in effect, that a proper Patent Office and Library, with accommodation for a collection of models of inventions, should be provided on the site named in the neighbourhood of Chancery Lane, and that the expense attendant thereon should be defrayed out of the surplus income of the Patent Office.

We further beg to bring under your Lordship's notice the fact that very great loss and delay are occasioned to manufacturers, inventors, and others, by the want of a complete classification and the prompt Indexing of all inventions, whether patented or not, Foreign as well as English. Such a systematic arrangement as is needed is quite within the compass of an efficient staff of officers possessed of technical knowledge, and could be at once proceeded with ; the state of inventions could then be ascertained, and the common case of several persons patenting the same thing would be avoided.

We trust your Lordship will pardon our now troubling you on these matters ; but the evils arising from the present most inefficient condition of the Patent Office are a source of constant loss of time and annoyance, and we therefore seize the earliest opportunity after the publication of the report of the Committee, to bring the subject most respectfully under your Lordship's attention ; and we trust that your Lordship will see fit to give such orders as will procure for the public the immediate and full advantages of the Patent Law Amendment Act of 1852, together with the erection of proper buildings for offices for the purposes of the Act.

In January 1853 certain Members of this Institution had the honour of addressing a Memorial to the then Commissioners of Patents on this subject, a copy of which we take the liberty to enclose.

November, 1864.

(Copy of the previous Memorial.)

TO THE RIGHT HONOURABLE FREDERICK LORD CHELMSFORD,
LORD HIGH CHANCELLOR OF GREAT BRITAIN ;
THE RIGHT HONOURABLE SIR JOHN ROMILLY, MASTER OF THE ROLLS ;
SIR FITZROY KELLY, HER MAJESTY'S ATTORNEY GENERAL ;
AND SIR HUGH MCCALMONT CAIRNS, HER MAJESTY'S SOLICITOR GENERAL.

The Memorial of the undersigned Officers and Members of the Institution of Mechanical Engineers humbly sheweth :

That it appears to your memorialists that a largely increased accommodation is urgently required for the numerous inventors, engineers, and others, who daily consult the official documents and the valuable free Library of the Great Seal Patent Office, and who desire to inspect the instructive models collected by the Superintendent of Specifications, to which additions have been continually offered from all parts of the United Kingdom.

That although recent alterations in the laws affecting patents have stimulated enquiries in every branch of knowledge connected with industrial arts, and the publications of the Commissioners have largely facilitated such investigations, yet the full benefit of these excellent measures cannot be realised so long as only the present small apartments are devoted to this national undertaking.

That the present Library is the only one in the United Kingdom in which the public have free access, not only to the records of the patents and inventions of this country, but also to the official and other documents relating to inventions contributed by numerous foreign governments, who have liberally responded to the desire of the Commissioners to promote international relations for the improvement of manufactures by the encouragement of inventions.

That it cannot but be a matter of regret that, while a surplus already large is continually accruing from the fees paid for patents in this country, the buildings devoted to the purposes of the Patent Office are insufficient in themselves, and contrast most unfavourably with those of foreign states.

Your memorialists therefore pray that you will be pleased to take such steps as may seem to you advisable for the erection and maintenance of a central commodious Patent Office worthy of this country, where ready access may be had to a Library, Reading Room, and Museum, furnished with the papers, books, and models indispensable to the right direction and advance of British Industry.

January, 1853.

The Minutes of the last Meeting were read and confirmed.

The CHAIRMAN announced that the President, Vice-Presidents, and five Members of the Council in rotation, would go out of office in the ensuing year, according to the rules of the Institution; and that at the present meeting the Council and Officers were to be nominated for the election at the Anniversary Meeting.

The following Members were nominated by the meeting for the election at the Anniversary Meeting:—

PRESIDENT.

ROBERT NAPIER, . . . Glasgow.

VICE-PRESIDENTS.

(Six of the number to be elected.)

JOHN ANDERSON, . . . Woolwich.
 CHARLES F. BEYER, . . . Manchester.
 WILLIAM CLAY, . . . Liverpool.
 THOMAS HAWKSLEY, . . . London.
 ROBERT HAWTHORN, . . . Newcastle-on-Tyne.
 EDWARD HUMPHRYS, . . . London.
 SAMPSON LLOYD, . . . Wednesbury.
 HENRY MAUDSLAY, . . . London.
 JOHN RAMSBOTTOM, . . . Crewe.
 C. WILLIAM SIEMENS, . . . London.

COUNCIL.

(Five of the number to be elected.)

PETER D. BENNETT, . . . Westbromwich.
 DANIEL K. CLARK, . . . London.
 EDWARD A. COWPER, . . . London.
 GEORGE HARRISON, . . . London.
 THOMAS HAWKSLEY, . . . London.
 EDWARD JONES, . . . Wednesbury.
 WALTER M. NEILSON, . . . Glasgow.
 CHARLES P. STEWART, . . . Manchester.
 JOHN VERNON, . . . Liverpool.

The CHAIRMAN announced that the Ballot Lists had been opened by the Committee appointed for the purpose, and the following New Members were duly elected :—

MEMBERS.

JOHN COWANS,	Carlisle.
JOHN CRAIGIE HALKETT,	Edinburgh.
THOMAS C. HIDE,	London.
WILLIAM WILSON HULSE,	Manchester.
EDWARD HUTCHINSON,	Darlington.
WILLIAM KIRTLEY,	Derby.
GEORGE LINDSLEY,	London.
WALTER MACFARLANE,	Glasgow.
ARCHIBALD FRANCIS MACNAB, . .	Birmingham.
LAWRENCE THOMSON MCEWEN, . .	Middlesbrough.
JOHN WILLIAM MIERS,	London.
JOSHUA LLEWELYN MORGAN, . . .	Aberdulais.
FREDERICK FRANCIS OMMANNEY, .	Manchester.
BENJAMIN LANGFORD FOSTER POTTS,	London.
JOSEPH D'AGUILAR SAMUDA, . . .	London.
CHARLES TENNANT,	London.
WALTER EVERS WARDEN,	Birmingham.

HONORARY MEMBERS.

JOHN TENNANT,	Glasgow.
FALKLAND SAMUEL THORNTON, . .	Birmingham.

The following paper, communicated through Mr. Frederick Levick of Blaina, was then read :—

DESCRIPTION OF A COAL CUTTING MACHINE.

BY MR. THOMAS LEVICK, OF BLAINA IRON WORKS.

The substitution of machinery for manual labour in our various manufactures and industries, the gradual development of railways, and the application of steam to navigation, have increased in a wonderful manner the demand for coal, that being the chief agent in the production of the motive power in all these cases. In the early periods of the working of the coalfields the produce of coal was very limited, the only means of conveying it from the pit to the shipping port being on pack horses carrying only 3 cwts. each, which were succeeded by the cart, increasing the load to 17 cwts. But by the introduction of railways the annual produce and consumption of coal in Great Britain was raised in 1855 to 64 millions of tons, in 1859 to 70 millions, and in 1860 to 80 millions; and according to Mr. Hunt's returns it has now reached the enormous quantity of nearly 90 millions of tons per annum.

Although coal has thus been so useful in promoting and extending the use of machinery, machinery has not yet returned the compliment by its application to the working of coal; it has only made various futile attempts, and only within the last year or two have any really practical attempts been made to lessen or supersede manual labour in working coal: the working or getting may in fact be considered to remain still in the same condition as in the pack-horse age. Machinery has certainly aided the increased production of coal by winding and pumping engines and by inclines above and below ground; but this kind of machinery has only facilitated the movement of the coal after it has been wrought by the collier. The actual working or getting it from the position in which it has been deposited in the mine ages ago is still accomplished only by

tools of the most primitive kind, plied by the strong arm of the sturdy collier under the most disadvantageous circumstances; for he has to wield the pick in a stooping or lying position, most unfavourable to the application of his muscular force, and this frequently in an atmosphere not only not remarkable for its purity but sometimes of a temperature as high as 80° to 90° Fahr.

The constant but gradual increase of temperature in penetrating the earth's crust, which takes place at the rate of about 1° Fahr. to each 60 feet of depth is well known. In the Monkwearmouth Colliery, the depth of which is 1800 feet, the temperature is 80° ; and this is considered to be as high as is consistent with the great bodily exertion necessary in the operation of coal mining. There is also an additional augmentation in the temperature of deep mines consequent on the increased density of the air, and this is about 1° for every 300 feet of depth. Certain portions of the coal in the deeper coal basins lie at depths approaching and even exceeding 4000 feet; and the temperature of the air at this depth according to the foregoing data would be 79° higher than at the surface, 66° being due to the depth and 13° to increased density of the air. The computations therefore of the duration of the coal-fields, as has been pointed out by Sir William Armstrong, require a considerable reduction in consequence of the impracticable depths at which portions of them are situated; and any means of increasing the practicability of working at these depths by the application of machinery becomes consequently a question of serious importance in reference to the duration of the coalfields, in addition to the advantages in economy of cost and time of working and in saving waste of material that are incident to the substitution of machinery for hand labour.

Many attempts have been made during a century past to construct coal cutting machines. One of the earliest was that of Michael Menzies in 1761, consisting of a pick fixed on the axle of a pulley placed near the face of the coal, to which a reciprocating motion was given by means of a chain passing round the pulley and connected with a steam engine at the surface, the pick performing

the operation of kirving or holing. He also invented a pick machine to be worked by hand.

In 1830 a battering ram for coal mines was proposed by William Wood. This was a heavy ram fixed in a sliding box acting on a wedge, the ram being worked backwards and forwards by manual labour.

The next to be noticed is a plan in 1843 consisting in applying rotary saws or picks driven by a winch or an engine for the purpose of severing blocks of coal from the surrounding mass. This was one of the first attempts for using rotary cutters, and the arrangements were complicated.

In 1846 a plan was proposed by Mr. W. H. Bell for suspending a heavy pick or chisel by a chain from a bar running along the face of the work at the roof, so as to be swung by hand against the coal.

In 1852 a machine was applied by Mr. W. D. Hedley, similar in its action to a planing machine, having a cutting tool projecting from the side of a carriage running on a railway, and the tool was made to cut deeper and deeper into the face of the coal by repeatedly traversing the carriage, and setting the tool at each successive cut to project more and more beyond the side of the carriage. There were holes in the machine at different heights for altering the tool according to the different heights at which the coal has to be cut.

About the same time a plan was proposed by Mr. C. H. Waring, in which reciprocating or revolving cutters are worked by compressed air or steam. The reciprocating cutters have somewhat the motion of planing or slotting machines, but the rotary cutters are fixed in the circumference of a wheel and act like a circular saw. The machine is arranged to cut either vertically or horizontally. The apparatus for applying the power is mounted on the frame of the machine, and consists of an oscillating cylinder worked by compressed air or steam.

In 1861 a pick machine to be worked by hand was proposed by Messrs. Ridley and Rothery, the pick working horizontally and vertically, and both motions being upon fixed axes; and about the same time a hand machine was proposed by Mr. Donisthorpe, in which the tool was a bar mounted on grooved rollers, giving it a rapid motion forwards and backwards.

The above are some of the principal attempts up to that time to work coal by machinery. They may be divided into reciprocating picks, sliding or planing picks, and rotary saws or cutters; none of them however have continued in practical use. The principal practical difficulty in the application of machinery to coal cutting is the confined space it is required to work in. Most of the machines above referred to occupy too much space and are generally too complicated for application in a coal mine; and machines made to be worked by hand, on account of the friction of the mechanism and the cumbrous arrangement, absorb too much manual labour to give them much or any advantage over the pick worked by the skilled collier.

Not until the last two or three years has anything practically useful been accomplished in the application of machinery to coal cutting; and Messrs. Donisthorpe Firth and Ridley's machine working at the West Ardsley Colliery near Leeds was the first machine which may be safely said to have demonstrated the practicability of cutting coal by machinery. This was one of the class of machines working with a pick, which was driven by a cylinder worked by compressed air; and it was followed by another machine, which introduced a trunk arrangement of the driving cylinder, so as to shorten up the connecting rod, thereby considerably shortening the machine, and enabling it readily to traverse the quick curves of mine tramroads, thus removing a serious practical difficulty previously experienced. Both these machines have been successful in performing one operation in coal cutting, namely "holing" or undercutting a seam of coal horizontally, and on a true plane or nearly so. But as they were constructed only to cut a groove horizontally, or rather parallel to the plane of the tramway, they were not adapted to meet the cases of inclined seams, so frequently occurring in practice; and as they were also limited to the horizontal undercutting, all vertical cutting that was required in the operation of getting the coal had to be done by hand work. These machines were inapplicable to driving headings; and for that purpose a modification of them has been made, having two pairs of vertical picks, one pair on each side

of the machine, and each pair consisting of one pick working upwards vertically from the bottom and the other working downwards vertically from the top, so as to make the two cuts meet one another. The undercutting however in driving the headings was still required to be done by the hand of the collier.

In order that a machine may be generally applicable to coal cutting, it should be capable of cutting in any direction, so as to work the "dip" or the "rise" or cut the vertical cuts. To do this, and at the same time to retain a simple form of machine, since complex machinery would be very objectionable underground, presented great difficulties; but these have now been entirely overcome in the coal cutting machine forming the subject of the present paper, which is the invention of Mr. James Grafton Jones of Blaina. In this machine the axis of the pick is carried in a revolving headstock, by which it is capable of being turned into any desired position by merely turning a handwheel at the end of the machine, the relative position of the pick and the air cylinder which works it remaining always the same. By this means the pick can be worked in any plane, either vertical, horizontal, or at any inclination; and it is thus enabled to cut the coal vertically in driving headings, and horizontally in holing, or in any inclined direction for working the dip or the rise when the seam of coal does not lie horizontally. Headings may thus be driven or any of the ordinary operations in the getting of coal or other minerals may be performed by the machine.

The machine is shown in Figs. 1, 2, and 3, Plates 82 to 84; Fig. 1 is a side elevation, Fig. 2 a longitudinal section, and Fig. 3 a plan.

The air cylinder A, Figs. 1 and 2, is placed horizontal, and is cast in one piece with the bed of the machine; and the piston B is forged solid upon the piston rod C. The lever pick D is keyed upon the transverse axis E carried in front of the cylinder A; and on the axis is a crank arm F, to which the piston rod C is connected by means of the slotted head screwed into the end of the rod, as shown in Fig. 2. The axis E is carried in bearings G G cast upon

the rotating headstock H; and this headstock is capable of being turned round in its bearings I I, by means of the handwheel J fixed on the shaft of the pinion K, Fig. 1, which gears into teeth on the headstock H. The pick D can thus be turned so as to cut the coal at any inclination whatever, the piston B turning in the cylinder when the headstock H is rotated; and when the pick is adjusted for working at any desired inclination, the axis E can be locked in that position by means of a pin passing through one of the holes in the handwheel J.

The slide valve L, Fig. 2, by which the compressed air is admitted to the cylinder A, is worked in one direction by the piston B, which on completing its back stroke strikes against the tappet rod M; this rod works through a stuffing-box in the back cover of the cylinder, and is connected to the lever N, the other end of which is connected to the slide valve stem. When the tappet rod M is struck by the piston, it moves the valve L into the position for admitting the compressed air to the back of the piston, for striking a blow by the pick. The valve is retained in this position until the blow has been struck, by means of a spring catch O, which is connected by a rod to the treadle P. An india-rubber spring R passes round the handle S formed on the lever N, and is attached by means of an adjustable joint to the platform T, on which the man working the machine is carried. When the treadle P is depressed by the man's foot, it releases the catch O, and the india-rubber spring immediately moves the slide valve so as to admit the compressed air to the front of the piston for making the back stroke; and another blow of the pick is then given by the piston striking against the tappet rod M. As the work progresses the machine is moved forwards by the handwheel U, which communicates motion by the bevil wheels V to the carrying wheels W of the machine.

From this description it will be seen that, at whatever inclination the coal may lie, the pick is easily put to work at that exact angle, whether to the rise or the dip. It may also be easily put to work at any part of the thickness of the coal, whether it be desired to hole at the bottom or at the top of the measure, or at a parting in

the middle or any other portion of the seam, by simply shifting the pick D, Fig. 1, to a greater or less distance upon the axis E on which it is keyed. Figs. 6, 7, and 8, Plate 86, illustrate the working of the machine, showing the pick in the position for holing, and also for making a vertical cut either downwards or upwards, as in driving headings. The position of the man working the machine is also shown, kneeling on the small platform at the tail of the machine, with his foot upon the treadle for releasing the slide valve, and holding the handwheel for advancing the machine between each stroke of the pick.

This machine when holing in the coal cuts a groove 3 feet deep, 2 inches wide at the face and $1\frac{1}{2}$ inch at the back; whereas a collier requires for effecting the same purpose to make a groove or rather excavation 10 to 12 inches wide or even more at the face, and tapering to the back. In doing this the collier is exposed to one of the most frequent and unavoidable dangers of the coal mine, by the large lump of coal breaking off and sliding down suddenly without warning, before he has completed his task.

The machine is calculated to work at the rate of 70 to 80 strokes per minute; and the one at work at the High Royd Colliery, Barnsley, under disadvantageous circumstances and in the hardest coal in the district, holes from 9 to 10 yards length per hour, 3 to $3\frac{1}{2}$ feet deep, including stoppages. In order to make the machine thoroughly effective, it is necessary that it should be on a good rigid road; but at this colliery it is working on the ordinary tramplate road loosely laid. The pressure of air at which it is worked is 30 to 35 lbs. per square inch. In the same seam of coal the collier does only 4 to 5 yards length of holing for a day's work, in place of the 90 to 100 yards done in 10 hours by the machine, the latter thus accomplishing fully twenty times the work that the collier can do by hand in the same time.

A second machine has just been put to work at the Oaks Colliery in the same district, in which an improvement has been made by the addition of a steadying apparatus, consisting of a tail piece which carries a pair of heavy rollers, as shown in plan in Fig. 4, Plate 85;

these rollers rest upon the tram rails and keep the machine steady under the vibration caused by the blows of the pick when striking laterally in holing. This tail piece follows with the machine when moving in a straight line; and it has the effect of lengthening the wheel base of the machine, and considerably reduces the lateral vibration on the road caused by the powerful blow of the pick when holing. It is readily detached when required to go round the short bends of the mine; and also when driving headings it is not required, as the pick is then working vertically. The machine at the Oaks Colliery holes at the rate of 14 to 15 yards length per hour, to a depth of $3\frac{1}{2}$ feet, the number of strokes averaging from 60 to 70 per minute, and the pressure of air being 35 to 37 lbs. per square inch. The road in this case is a railroad thoroughly well laid.

These machines are also well adapted to work in the ironstone shales and to quarry Bath stone; indeed the pick would work in anything softer than its own point.

The use of compressed air for working underground machinery is not new, though it is only recently and since the introduction of coal cutting machinery that it is being more extensively employed. The first practical employment of it in this country was at the Govan Colliery near Glasgow in 1849; the machinery was erected by Messrs. Randolph Elder and Co., and a description of it was read before this Institution at the Glasgow Meeting in 1856 (see Proceedings Inst. M. E., 1856, page 145). At the Haigh Colliery near Wigan two air-compressing engines were also employed, the air being compressed to 120 lbs. per square inch, and carried down a shaft 234 yards deep, and to a distance of 500 yards from the bottom of the shaft. The engines worked by the compressed air at this colliery and at the Govan Colliery were employed for winding underground.

A peculiarity attendant upon compressing the air is the heat developed during compression, which increases rapidly with the pressure. Thus air, which at the atmospheric pressure of 15 lbs. is at 32° Fahr., would be raised to 110° by being compressed to 30 lbs. per square inch; and at 120 lbs. per square inch, the effective

pressure in the Haigh engines, the theoretical temperature would be about 450° . A special provision to meet this circumstance is mentioned hereafter. An inconvenience in working these compressed-air engines was the liability of the air passages and exhaust pipes to become clogged with ice, in consequence of the water suspended as moisture in the air being frozen by the cold produced in the sudden expansion of the exhaust air. This is avoided in the coal cutting machines by making the slide valve with sufficient inside lap to cause the exhaust air to escape slowly at each stroke, thereby preventing its sudden expansion; and this arrangement, combined with the concussion caused by the stroke of the pick, prevents the exhaust passages becoming clogged with ice. In an air engine at Dowlais, when the air was escaping under a pressure of 15 lbs., the temperature of the exhaust air was 29° Fahr.; and the greater the pressure, the greater will be the cold produced in expansion.

There is a loss of power in air-compressing engines, arising from leakage and friction in the air pipes, and the mechanical power lost in the form of heat when the air is compressed. The loss from leakage and friction is very small, and if the joints are good, that from leakage will be inappreciable; but the loss from the escape of heat is great. The cylinder in which the air is compressed gets so hot that it is necessary to keep it surrounded with water, the temperature increasing with the pressure to which the air is compressed; and on the other hand when the compressed air has done its work and is allowed to escape, a degree of cold is produced which freezes any moisture that there may be in the exhaust passages. By the compression of the air its capacity for heat becomes diminished; consequently a portion of the latent heat already contained in it at its natural pressure is developed in the form of sensible heat, and this is absorbed by the cylinder and the surrounding water. The air itself does not get sensibly hotter, since only its capacity for heat is changed by the compression, while the excess of heat developed by its compression is rapidly absorbed by the surrounding metallic surfaces which conduct it away. When this air has done its work and expands again to

its original pressure, its original capacity for heat returns; and the quantity of heat then contained in it not being sufficient for maintaining the same temperature in its expanded form, it consequently draws heat from the surrounding bodies, thus producing cold. The amount of heat thus absorbed in the act of expansion is the exact equivalent of that which is developed during compression; but the heat developed in compression being lost by conduction, the amount of power equivalent to it is also lost.

Fig. 5, Plate 85, shows a longitudinal section of the air-compressing engine, of a size suitable for working four to six coal cutting machines. It consists of two cylinders, one the steam cylinder and the other the air cylinder, fixed horizontally on the same bedplate, the piston rod of the steam cylinder being directly attached to the piston rod of the air cylinder. The steam cylinder A is $16\frac{1}{2}$ inches diameter and $3\frac{1}{2}$ feet stroke. The air cylinder B is surrounded by water to keep it cool. The compressed air passes through the delivery valves C C into the pipe D leading to the mine. The inlet valves are fixed on the side of the air cylinder, and are similar to the delivery valves. The slide valve of the steam cylinder is worked by a tappet, as there is no crank or flywheel to the engine. The speed of the engine is regulated according to the number of the coal cutting machines at work: when all six machines are at work, the speed of the piston is from 250 to 300 feet per minute.

The effect produced upon the ventilation and temperature of the mine by the supply of air from the discharge of the coal cutting machine may now be considered. When the machine is working at 60 blows of the pick per minute, it will discharge 24 cubic feet of air per minute at a pressure of 45 lbs. per square inch, which by expansion becomes 72 cubic feet of air at the atmospheric pressure and at a temperature below freezing point. Taking the quantity of air passing along each face of work in the mine at an average of 6000 cubic feet per minute at a velocity of 4 feet per second, the quantity of air discharged by each machine would be only $1\frac{1}{4}$ per cent. of the whole amount. Supposing the temperature in the mine,

as at Monkwearmouth, to be about 80° Fahr., it would be reduced only 1° when thoroughly mixed, but it would be considerably cooler round the point of issue. The ordinary ventilating current has frequently had to travel considerable distances, and has acquired a great deal of impurity and a high temperature before it reaches some of the faces of work. But supposing three or four machines to be employed along each face, the current instead of becoming impure would retain its purity and become cooler.

A collier when at work breathes heavily, and inhales about 28 cubic feet of air per hour, and exhales about 1 cubic foot of carbonic acid in the same time. One coal cutting machine may be said to save the work of 20 colliers, who would inhale 600 cubic feet of air per hour; while the machine supplies 4320 cubic feet per hour of cold and pure air at the place where it is most required.

The firedamp in a mine having only half the specific gravity of air is very apt to float above the passing current of air, instead of mixing with it, especially where there is any unevenness in the roof forming cavities in which the firedamp can lie stagnant. The violent agitation however produced by the discharge of air from the coal cutting machine will aid materially in the intermixture of the gas with the current of air, and the discharge of air from the machine may be directed to any particular point, as desired.

The advantages of cutting coal by this machine may be summed up as follows:—

1st. The saving of a large percentage of small coal in the process of holing, and a corresponding increase in the proportion of large coal obtained.

2nd. The economy in the cost of getting the coal.

3rd. The improvement in the ventilation and temperature at the working points.

4th. The facility with which headings may be driven and ventilated, the machine itself supplying air sufficient for several men and at a low temperature. The machines being well adapted for driving headings, collieries may be opened and won to their outside boundaries in a much shorter time.

5th. The saving of life and limb to the collier, by removing him from the most perilous portion of his occupation, that of holing or undercutting the seam of coal.

6th. The power of carrying the working into the deeper seams of coal, which lie at so high a temperature as to present serious difficulty in the way of performing the severe labour of cutting the coal by hand work.

Mr. F. LEVICK exhibited a model of the coal cutting machine, illustrating the action of the pick in cutting the coal at any inclination by means of the revolving axis carrying the tool.

The CHAIRMAN remarked that the application of machinery to coal cutting was a subject of great importance, and there could be no doubt that ultimately coal cutting machines would greatly assist manual labour, by performing the most difficult and dangerous work of undercutting the coal. In the machine described in the paper just read, the principal feature appeared to be the arrangement by which the tool was turned round to work at any inclination, thus affording the means of cutting the coal at any angle. The machine was otherwise similar to that of Messrs. Donisthorpe Firth and Ridley, which was now working at the West Ardsley Colliery near Leeds, and he believed that was the first instance in which machinery had been successfully brought into practical operation for coal cutting by the use of compressed air actuating a pick; the machine was capable of being worked in any part of the mine by compressed air supplied to it from an engine at the surface.

Mr. W. MATHEWS had not had an opportunity of seeing coal cutting performed by machinery, but was satisfied that if the application of machinery to that purpose could be practically accomplished it would prove a most important benefit in coal mining. The recent struggle with the colliers in South Staffordshire was a sufficient proof of the necessity of adopting machines for cutting coal in place of manual labour.

Mr. SAMPSON LLOYD enquired what effect the great variety in the thickness of the seams of coal in different districts would have upon the applicability of the machine now described; and whether, if successfully employed in one district with a certain thickness of seams, the same machine could be made equally applicable in another where the seams were of a very different thickness.

Mr. C. COCHRANE thought one of the difficulties attendant upon different thickness of seam would be felt in applying the coal cutting machine in South Staffordshire, owing to the different method employed in cutting the Thick coal. In undergoing the Thick coal the practice was to cut away a thickness of $2\frac{1}{2}$ feet, and this was all sacrificed as slack, and had to be excavated in order to allow the collier to go in under the coal for performing the holing, which was carried to a depth of 10 or even 20 yards in from the face. The machine in undercutting the coal to a distance of 3 feet in from the face excavated a groove only a few inches thick, which he thought would be found quite inadequate in the Thick coal to allow of breaking the coal down afterwards. If the present system of working were carried out, the machine would be required to be arranged so as to excavate a thickness of $2\frac{1}{2}$ feet, and afterwards go into the excavation so made and undercut the coal still further from the face; and he thought there would be some difficulty in using the machine in that way. Before adopting the machine, information was needed respecting its durability, as to whether that had been fully tested by actual working; and also in reference to the total outlay for plant in cutting coal by a machine of the size shown in the drawings.

Mr. F. LEVICK explained that the machine excavated only 2 or 3 inches thickness of coal in undercutting the coal to a distance of 3 feet in; and the coal so undercut could then be benched down for a height of $2\frac{1}{2}$ feet, if desired; after which the machine could go under and proceed with the holing 3 feet further in, and so on to any extent of undergoing that might be desired, since the machine was made low enough to enter into any space $2\frac{1}{2}$ feet high, and could thus go under the coal wherever a collier could work in the ordinary system of holing. The great advantage however of the

machine over the collier was that, while the whole thickness of $2\frac{1}{2}$ feet was converted into slack by the collier, in order to cut an excavation large enough to admit him to go under, the machine converted only 2 or 3 inches thickness into slack, and the remainder of the $2\frac{1}{2}$ feet thickness was obtained in the form of good serviceable coal. The machine shown in the drawings was low enough to work in a height of only $2\frac{1}{2}$ feet; but it could be made considerably lower by diminishing the size of the carrying wheels and otherwise modifying the construction. In undercutting the coal, the axis of the pick was turned so as to bring the pick into its lowest position, enabling the pick to excavate the coal as low down as on a level with the rails.

Mr. W. HADEN did not see what need there was to undergo the coal to a greater depth than 3 feet from the face before benching it down. It was true that was not in accordance with the very antiquated mode of working the Thick coal which was still adhered to in the South Staffordshire district; but he did not think there was any real necessity for working the Thick coal in a different manner from that adopted in thin seams, as regarded the mode of holing, and the machine might just as well be employed in the Thick coal for undercutting to a depth of 3 feet, after which the coal so undercut could be benched down to any height that was desired. He enquired whether the machine could cut vertically, so as to cut down the sides of a block of coal after undercutting it, which would then allow of benching the coal down easily in the case of driving a heading.

Mr. C. COCHRANE thought the machine was best applicable for undercutting thin seams of coal, where the creeping of the roof had the effect of breaking down the coal as the work proceeded. In applying this machine however to the lower portion of the Thick coal there would be no such creep, the thickness of coal above being so great as to prevent any practical deflection; and thus the difficulty would arise as to how the coal so undercut could be broken down; and furthermore how, if that were effected, the large masses of coal could be conveniently broken up into pieces sufficiently small for a man to lift. One advantage of the deep

excavation made by a collier in holing the Thick coal, notwithstanding the quantity of slack produced, was that the act of dropping the seam above broke the coal up into masses which did not require much further trouble to make them small enough to be handled in the usual way.

Mr. F. LEVICK explained that, by turning the pick round so as to work vertically, the machine would cut the coal vertically in the same manner as it performed the holing. It was not intended however for breaking up the large masses of coal after they were benched down, and that operation as well as loading the coal into the trams would have to be done by hand labour, as at present.

Mr. F. SMITH observed that it appeared from the explanations which had been given that the machine was as applicable as manual labour to the purpose of undercutting the coal, to the extent of even $2\frac{1}{2}$ feet thickness, by excavating two horizontal cuts at top and bottom of that thickness, and then benching down the coal between; and the difference between the two modes of holing was the important practical advantage obtained with the machine in getting nearly all that thickness of coal in the useful form of lump coal, instead of its being all converted into slack as was done by the collier.

Mr. W. MATHEWS enquired what was the thickness of the seams of coal at the collieries where the machine had been adopted, and what was the character of the coal cut, and the lay of the seams. In working seams of coal up to 4 feet thick, if the holing were carried in to a distance of 3 feet from the face by the machine, that would no doubt allow of benching down the remaining thickness of the seam: but with the South Staffordshire Thick coal of 30 feet thickness he thought a holing extending only 3 feet in under the coal would not be far enough to allow of bringing down the greater thickness that was usually benched down at a time, and it would be necessary for the undergoing to be carried further in. Moreover there was a great difference between hard and soft coal, as to the success with which it could be worked by a machine: for he understood that the trials made by Mr. Nicholas Wood with a coal cutting machine at his collieries in Durham had proved successful

with the soft coal, but not with the hard coal, as the machine worked so much slower in the hard coal. The lay of the seams also, instead of being always horizontal, was frequently at an inclination, the slope of which was varied by waves in the seams; and in many localities the course of the seams was interrupted by faults. In working such seams by manual labour the collier could employ his pick in such a manner as to meet the requirements of any case that might arise; but a machine was not so readily adapted to all varieties of circumstances.

The CHAIRMAN said the seams of coal worked by the machine at the West Ardsley Colliery were about 5 feet, 3 feet, and 2 feet 9 inches thick, and the machine was equally applicable for cutting the coal in all of them. The machine used in that case was smaller than the one shown in the drawing, and could cut the coal only horizontally or vertically, but not at an inclination. The earlier machines had been rather too small, but they might be made of any size that was most suitable for the mine in which they were to work.

Mr. F. LEVICK explained that, whatever might be the inclination at which a seam of coal lay, it could be cut with equal facility by the machine, since the pick worked either horizontally or vertically or at any inclination between those extremes, with equal readiness in all positions. In the case of a colliery in Glamorganshire, where the dip of the coal was at an inclination of 45° , it had been decided, instead of sinking a vertical shaft in the ordinary manner, to sink an inclined shaft at 45° following the dip of the coal, by means of some of these coal cutting machines which had been ordered for the purpose. As regarded the application of the machine to the Thick coal of South Staffordshire, he remembered that the plan in use many years ago for working the coal had been to work it in successive stages, commencing from the bottom and working upwards; and in places where the Thick coal was so worked, the machine would answer the purpose of undercutting in the bottom stage. In reference to the practical working of the machines, one of them had now been at work at the High Royd Colliery near Barnsley for the last three months, which was of the

size shown in the drawings, and he understood had proved thoroughly successful.

Mr. S. BAILEY had seen the coal cutting machine at work both at the West Ardsley Colliery and at the Hetton Colliery, at both of which collieries the machine was the same as that described in the paper, excepting that the latter had the important improvement of the revolving axis, enabling the pick to be worked at any inclination so as to cut the coal either in seams lying level or inclined. He had been much pleased with the working of the machines at both places, and had noted the particulars of two pieces of work that he had seen done by the machine at the Hetton Colliery, undercutting the coal in the High Main seam, which was a very hard quality. The holing was performed at three separate cuts, with a different tool each time; and in the first piece of work a length of 6 feet along the face of the coal was undercut by the machine to a depth of $2\frac{1}{2}$ feet in from the face in $18\frac{1}{2}$ minutes, the particulars of each cut being as follows:—

1st cut	.	.	.	19 inches deep	.	.	in 9 minutes.
2nd „	.	.	.	5 „ „	.	.	in $4\frac{1}{2}$ „
3rd „	.	.	.	6 „ „	.	.	in 5 „
Total depth of cut.				<u>30</u> inches deep	.	.	in <u>$18\frac{1}{2}$</u> minutes.

In the second piece of work a length of 3 feet along the face was undercut to a depth of 3 feet in from the face in $11\frac{1}{2}$ minutes, as follows:—

1st cut	.	.	.	19 inches deep	.	.	in 4 minutes.
2nd „	.	.	.	12 „ „	.	.	in 5 „
3rd „	.	.	.	5 „ „	.	.	in $2\frac{1}{2}$ „
Total depth of cut.				<u>36</u> inches deep	.	.	in <u>$11\frac{1}{2}$</u> minutes.

The time noted included the time of exchanging the picks between each cut, and moving the machine back again to the starting point for each separate cut. From these specimens of its performance he was very well satisfied with the working of the machine, and was confident that its adoption in any district would be attended with very considerable advantage in coal mining.

Mr. T. LEVICK had seen one of the new machines started to work only two days previously at the Oaks Colliery near Barnsley, in a

seam of coal about $5\frac{1}{2}$ feet thick, where it was working along a road laid in the direction of the dip of the coal. That was the first time that one of the machines had been applied upon an inclined road, and there was rather a difficulty in keeping the machine back in working; it had a tendency to run forwards down the incline of the road, which somewhat interfered with the pick clearing itself readily from the coal after it had struck the blow, and the pick was apt to jam itself in the groove it had cut. Notwithstanding this drawback however the machine on that occasion undercut a length of 14 feet in 7 minutes at the first cut, to a depth of 15 inches in from the face. The machine at the High Royd Colliery near Barnsley had now been at work for some months, and it was calculated that it did the work of rather more than twenty colliers; the coal it was working in was $8\frac{1}{2}$ feet thick at that colliery.

Mr. F. SMITH enquired whether the coal was benched down after passing the machine once along the face and undercutting once with the pick.

Mr. T. LEVICK replied that the machine was passed twice or three times along the work, until the coal was undercut to the depth of 3 feet in. After making the first cut the machine was taken back to the place from which it started, and the first tool was removed and replaced by a longer pick rather thinner at the point; this did not cut the groove any wider than the 2 inches excavated by the first cut, but only deepened it. After the undercutting had been carried to the depth of 3 feet along the whole length of the cut, the coal was benched down.

Mr. J. E. SWINDELL asked whether in a seam as thick as 5 feet the coal could be benched down with only so small a thickness as 2 inches cut out at the bottom by the machine.

Mr. T. LEVICK replied that an instance of that sort had occurred at the High Royd Colliery, where the coal could not be benched down with only 2 inches thickness excavated in undercutting.

Mr. J. G. JONES said that in such a case it was intended to put on a cleaver or axe instead of the pick, and fix it for working on the upper end of the axis of the machine, cutting downwards in an inclined direction towards the first holing, so as to cut out a wedge-

shaped block of coal; for it was found that in benching down so much as 5 feet thickness of coal at once, the excavation of only 2 inches width made by the pick of the machine was not enough to allow so thick a block of coal to break off, or if it did break off it lodged and could not be readily got out. By cutting out a wedge of coal however with the cleaver, the holing was made as wide at the face as was done by the collier, with the important advantage that the piece of coal so cut out by the machine was obtained as good serviceable lump coal, instead of being all broken up into slack in the process of holing by manual labour.

Mr. J. FERNIE enquired how the forward movement was given to the machine, for advancing it as the work progressed.

Mr. T. LEVICK explained that the forward motion was given by the handwheel on the top of the machine, geared to the carrying wheels, by means of which the machine was advanced by hand the required distance after each stroke of the pick. Before advancing the machine however after each stroke, it was first drawn back slightly by the handwheel, so as to ease the pick out of the cut, and allow of the return stroke being made readily; the action thus produced was similar to that of a collier working a pick by hand.

Mr. J. E. SWINDELL asked in what manner the machine would be put to work for driving a heading of $3\frac{1}{2}$ feet square, in front of the machine itself.

Mr. T. LEVICK said for such a purpose the pick was started cutting vertically downwards, being fixed first on one end of the axis and afterwards on the other, so as to cut a vertical groove on each side of the heading. The axis of the pick was next rotated, so as to make the pick cut horizontally, and the machine was drawn back to the full length of the pick, which then cut a horizontal groove at bottom and top of the heading, so that the cubical block of coal was cut on all four sides, and held only at the back, and was readily broken off and removed.

Mr. G. ADDENBROOKE had seen the machine at work at the West Ardsley Colliery more than a year and a half ago, and it appeared to be doing its work admirably, irrespective of the question of cost of working. The seam of coal in which it was then working

was $3\frac{1}{2}$ feet total thickness, having a parting in it less than 1 foot thick in which the machine was performing the holing for getting the upper half of the seam of coal first. He enquired what was the cost of the coal cutting machine and the air engine for working it.

Mr. F. LEVICK replied that the heaviest part of the expense was the air-compressing engine, which however was of simple construction, as seen from the drawing; and the cost of an engine of the size there shown, with steam cylinder 16 inches diameter and $3\frac{1}{2}$ feet stroke, was not more than £250. The size of steam cylinder however would of course depend upon the pressure of steam intended to be employed. The cost of the coal cutting machine was about £60 or £70, exclusive of royalty.

Mr. G. ADDENBROOKE enquired whether there was not rather a heavy expense in conducting the compressed air from the engine to the machine. At the place where he had seen the machine at work in the West Ardsley Colliery there was about 40 feet length of vulcanised india-rubber tubing at the machine, as the air tube was required to be flexible at its extremity, to allow the machine to move backwards and forwards; and he had noticed that there was a great deal of leakage, consequent on its working backwards and forwards over the rough floor of the mine.

Mr. T. LEVICK thought the leakage of air would be small, if the pipes and joints were properly constructed in the first instance. The size of the pipes necessary to convey the air to the machine was so small that the expense on that score would not be considerable. At the Oaks Colliery, where it was intended to use the machines on an extensive scale, the pipes had been made larger than would otherwise have been necessary; they were 5 inch cast iron pipes from the air-compressing engine to within 400 yards of the machine, then $2\frac{1}{2}$ inch cast iron pipes nearly to where the machine was working, and thence $1\frac{1}{4}$ inch gas piping with an india-rubber hose at the end; so that practically a $1\frac{1}{4}$ inch pipe was amply sufficient for working one machine well. At the High Royd Colliery much smaller pipes were used, the pipe from the engine being only $1\frac{1}{2}$ inch diameter; and a 2 inch gas pipe would be large enough for supplying two or three machines with air.

Mr. F. SMITH enquired whether the air-compressing engine could be worked by the winding engine of the pit, instead of having an independent steam cylinder for the purpose. He asked also whether in undergoing the coal the point of the pick cleared its own course, in undercutting by the machine: a collier in holing gave two motions with the pick, the first being the actual striking of the blow, and the second a sort of drawing motion, drawing out the small coal from the cut.

Mr. J. G. JONES replied that it was objectionable to attach the air-compressing cylinder to the winding engine, because the interruptions in the regular working of the engine would interfere too much with the regular working of the coal cutting machine; but it might be attached to the pumping engine, if it were desired to avoid having an additional steam cylinder. The required movement for enabling the point of the pick to clear itself after each blow was given by the man working the machine, who brought the machine back a little after each stroke by means of the handwheel, so as to free the pick out of the groove; and the pick brought a small quantity of small coal out with it at each stroke.

The CHAIRMAN remarked that at the West Ardsley Colliery the exhaust air from the coal cutting machine was blown into the cut, which effectually blew out all the small coal and dust and kept the groove clean for the pick to work in. At first the air was blown in alone, and the coal at that colliery being of a dry quality, the effect was to smother the men with dust; and then a little water was blown in with the air, which completely laid the dust, while clearing out the dirt.

Mr. J. G. JONES had not found it necessary to blow in water with the air at other collieries where the machine was employed; but some coal was much more dusty than others, and in that case a little water should be used with the air for blowing out the cut.

Mr. J. E. SWINDELL enquired whether the saving effected in cutting the coal by the machine as compared with manual labour had been ascertained from the working of the machines at the collieries where they were in use.

Mr. F. LEVICK was not aware what was the amount of the saving effected by employing the coal cutting machines; but that there was a considerable saving was shown by the fact that at the collieries where they were already adopted it was intended to use them still more extensively in place of manual labour. Already one machine did the work of 20 or 30 colliers in holing, and he expected it would ultimately be made to accomplish even more.

Mr. G. ADDENBROOKE remarked that, even if the machine had cost more than manual labour, it would have been of the greatest advantage in the South Staffordshire district to have a number of the machines ready to be put to work during the recent colliers' strike.

Mr. J. M. HETHERINGTON said a rough estimate of the saving effected by the machine might be obtained by comparing the wages paid to colliers and the cost of the machine. In Lancashire the average wages of a collier were 30s. per week, amounting to about £75 per year; and the cost of four machines, complete with air-compressing engine and pipes to the machines, might safely be estimated at an outlay of not more than £1000. Thus $7\frac{1}{2}$ per cent. interest on the outlay would be realised upon the labour of every collier saved by the machines; and as one machine was found to perform the work of 20 men in holing, it was clear that a considerable number of men might be dispensed with by the adoption of the machine, with a large saving in the cost of getting the coal.

Mr. ISAIAH HILL thought the question was only one of cost, as to the adoption of the coal cutting machine, since there appeared to him no doubt about its advantages over manual labour, and it had only to be considered what would be the expense of putting the machine to work and keeping it in good order. It would be particularly serviceable in mines worked on the long wall system; and where the pits had straight roads the expense of working the machine he thought need not be much; but in pits worked with gob roads for bringing out the coal through the goaf, as was commonly the case in long wall workings, there would probably be a good deal of expense involved in constantly taking up the air pipes as each gob road in succession was abandoned, and relaying them in the

new roads as the working faces advanced. Notwithstanding this additional trouble however he thought the machine might be advantageously brought into use in such cases. It would also be especially applicable wherever there was the good fortune of meeting with a considerable extent of a level coal seam not interrupted by faults, in which case it might be put to work with great advantage to undercut along a great length of face, where otherwise as many as 20 men in a row might have to be employed for holing the coal. There would probably be much difficulty in using the machine in places where there were many faults, from the trouble of constantly shifting the machine to work in different positions, and the difficulty of obtaining a sufficient length of working face to render the employment of the machine remunerative.

Not only would the machine effect a great saving in undergoing the coal, by obtaining good solid coal where the collier made small slack, but this saving would be particularly important in the case of thin coal seams, say only 3 feet thick or less, in which at present the collier cut away about 18 inches thickness at the face and converted it into slack. And with regard to undergoing in the Thick coal of South Staffordshire, of which he had had experience in the workings under his charge at the Chillington Collieries near Wolverhampton, as the chief amount of labour was in the undergoing, he did not see why the machine should not be made serviceable for the purpose, by adding a longer pick if it were desired to carry the holing further in from the face before benching down the coal. The thickness of 2 inches excavated by the machine appeared to him to be in general quite sufficient for getting the coal down, as it must be a very hard coal indeed that would not break off with 2 inches of undercutting at the face carried to a depth of 3 feet in. No doubt the mass of coal benched down with only 2 inches thickness of holing, would "lie in the dirt" as it was called, that is, would remain almost in the same place after being broken down, instead of falling forwards from the seam: but it would be none the less completely broken down and loosened from the seam, and could be broken up and got out by the colliers in the usual manner. In working very hard coal, it was frequently necessary to blast it with powder, and when that

was the case he suggested that the machine might be made use of for drilling the holes for the charges. The machine would also be very useful he thought for many other parts of the work done in a pit, particularly for driving small headings or gateroads; and as the quantity of small coal made by the machine was so much less than in hand labour, he thought this might all be used up in the puddling furnaces.

Mr. T. LEVICK explained that in working a very hard coal, which would not break off with only 2 inches thickness of holing, the coal was got down by putting a cleaver or axe on the machine, as had been mentioned, after first undercutting with the pick; by that means a wedge-shaped piece of coal was cut out to the height of $1\frac{1}{2}$ or $2\frac{1}{2}$ feet, which had the same effect as undergoing the coal to the same height by hand labour, and saved the coal instead of reducing it to slack. This had been done at the High Royd Colliery for benching down the coal in the $8\frac{1}{2}$ feet seam, and the original 2 inch groove cut by the machine was afterwards widened by the cleaver to 18 inches at the face of the coal.

Mr. F. SMITH did not see why the length of the pick should be limited to 3 feet, and he enquired whether a greater length of pick had been tried with the machine, for undergoing the coal to a greater distance in from the face. He asked also how many men were required for working the machine, and in what spirit it had been received by the colliers at the pits where it was already at work.

Mr. T. LEVICK replied that in working the machine with a long pick, as the wheels were kept close together under the body of the machine, it had a great tendency to jump off the rails at each stroke of the pick in holing; but this had now been effectually obviated by the addition of the steadying tail-piece attached behind the machine, which produced a great improvement in the steady working of the machine, preventing vibration in holing, and allowing of keeping the carrying wheels close together under the machine. The greatest length of pick yet worked by the machine was $4\frac{1}{2}$ feet, but 3 feet was the longest ordinarily used. The machine required only one man or a boy to work it:

The CHAIRMAN said he had understood the men working at the collieries where the machine was used liked it because it brought them a constant and very abundant supply of fresh cool air into the workings. It would of course be an expensive undertaking under ordinary circumstances to keep the mine cool for the men, but with the coal cutting machine the owner of the colliery could not avoid throwing cold air into the workings. The way in which the machine had been worked at some collieries where there was a night shift was to undergo a lot of coal in the night, and then the men went down the pit in the morning to get it during the day. With regard to the great advantage and economy of the machine as compared with hand labour, it should be borne in mind that one principal reason of the superiority of the machine was that the pick when worked by the machine was guided at each blow with perfect accuracy, and the full force of the blow was concentrated on a narrow pick, so that it cut a much narrower groove than the collier could possibly do, and was thus enabled to undercut a much greater length of coal in the same time ready to be benched down: the first pick cut a groove of only 2 inches width, the second $1\frac{5}{8}$ inch, and the third a groove only $1\frac{1}{4}$ inch wide. The average width of the groove from the face to the innermost extremity was therefore not so much as 2 inches, and it was only this very small portion of coal that had to be cut out in slack by the machine, in place of the large excavation required to be made by the collier for undergoing the coal to the same distance in. The machine was thus in fact not a coal crushing, but literally a coal *cutting* machine.

Mr. SAMUEL LLOYD enquired how many of the machines were now at work, and whether in any instance where they had been introduced they had afterwards been discarded.

Mr. F. LEVICK said there were only two of the machines yet at work in the present form, but a number more were in progress; and there were as many as twenty or thirty holing machines in use upon the previous construction, before the improvement of the rotating headstock had been added, for enabling the pick to work at all inclinations. No one who had once tried the machine had discarded it, and all who had already got it at work intended to employ it more extensively.

The CHAIRMAN suggested that, if one of the machines were shown at work in the South Staffordshire district, that would be a satisfactory mode of practically testing its capabilities and advantages.

Mr. F. LEVICK said one of the machines had been shown at work above ground in Manchester, and had been tried upon a block of Bath stone for the purpose, from the bottom of which it cut out a groove of 2 inches width with great facility, quite smooth and clean.

Mr. F. SMITH said that at the Earl of Dudley's collieries he should be happy to arrange for affording every facility for a thorough practical trial of the coal cutting machine.

The CHAIRMAN proposed a vote of thanks to Mr. Levick for his paper, which was passed.

The following paper, communicated through Mr. Edward Jones of Wednesbury, was then read :—

ON PUDDLING IRON BY MACHINERY.

BY MR. HENRY BENNETT, OF WOMBRIDGE IRON WORKS.

In the manufacture of wrought iron from the crude pig iron, the purifying of the metal by the process of Puddling involves very heavy and long continuous hand labour; since the metal, after being melted in the puddling furnace, has to be continuously stirred for a considerable time whilst boiling, in order to expose it thoroughly to the action of the current of air passing through the furnace, so as to effect the chemical changes required for the separation and removal of the impurities originally combined with the iron. The metal has then to be balled up into separate masses of about $\frac{3}{4}$ cwt. each for the shingling hammer; and the whole process extends over about an hour from the time of melting the pig iron for each heat, of which six are worked in the day.

The application of machinery to puddling has long been felt to be very desirable, on account of the laborious nature of the process, owing to the continuous heavy work required and the great heat to which the men are exposed; and the simple mechanical character of the greater portion of the process, which consists in merely a continuous uniform stirring of the material, renders it very suitable in that respect for the application of machinery. But the high temperature of the furnace and the necessity for not interfering with the current of air passing through it, which has to be regulated and changed as the process advances, cause great practical difficulties in successfully carrying out the application of machinery in place of hand labour.

Many attempts have been made to accomplish puddling by machinery. A rotary furnace has been tried, having the portion containing the melted iron made to revolve by machinery horizontally upon a vertical axis, with a scraper placed across it for

stirring the metal as it revolved, the object being to effect the entire operation by machinery; but the practical difficulties in keeping such a machine at work and obtaining the proper result in the process were found too great to be surmounted. Various attempts have also been made to produce an action similar to that of the hand puddling process, by means of machinery more or less complicated; but it is important that any apparatus for the purpose should be simple in construction, and not liable to get out of order under the rough usage of the men by whom it has to be worked.

In the plan to be described in the present paper, the object of the writer has been to adhere as closely as possible to the ordinary course of hand puddling, and to employ machinery simply to aid the puddler by relieving him of the most laborious part of the work, namely the stirring or working of the metal in the puddling furnace. At the same time the objects aimed at have been, by a more rapid and uninterrupted process of stirring the metal, to shorten the time of the puddling, thereby economising fuel; to improve the quality of the iron, by rendering the process more uniform and perfect than with hand labour; and to increase the yield of the furnace, by working larger charges than could be both puddled and balled up at one heat by hand labour alone.

The apparatus is shown in Figs. 1 to 4, Plates 87 to 90, which represent it as applied to a double puddling furnace worked from both sides. Fig. 1 is a transverse section of the furnace, Fig. 2 a plan of the top of the furnace showing the machinery, Fig. 3 a longitudinal section of the furnace, and Fig. 4 a sectional plan showing the area worked over by the machine.

The ordinary puddling tool or "rabble" A A, Fig. 1, is worked backwards and forwards in the puddling furnace by the vertical arm B B outside the furnace, to which it is connected by a notch in the handle of the rabble, dropped loosely upon a pin at the bottom of the working arm. This arm is cotted at top into a horizontal square slide bar C C overhead, sliding longitudinally through two guide sockets D and E, and worked by the connecting rod F F from the main bar G G, which is a long T iron bar extending horizontally across a

whole row of puddling furnaces, being carried by rollers *II* in the frame fixed upon each furnace; and a longitudinal reciprocating motion is given to it by a crank at one end driven by engine power. The guide frame or sector carrying the guide sockets *D* and *E* of the sliding bar *C* is centred on a vertical pin immediately over the door of the puddling furnace, and the outer end is moved transversely from side to side with a slow reciprocating traverse along the guiding quadrant *H*, Fig. 2, by means of the connecting rod *J* from the crank *K*, which is driven through a worm wheel and screw *L* by the horizontal shaft *MM* extending over the furnaces alongside the reciprocating bar *G*.

The main bar *G*, Fig. 1, works at a speed of about fifty strokes per minute, and has a length of stroke of 2 ft. 10 ins., carrying the rabble with the same length of stroke across the floor of the furnace, as shown by the two extreme positions in the transverse section, Fig. 1, and the sectional plan, Fig. 4. The transverse motion given by the crank *K*, which makes one revolution for every seventy strokes of the rabble, causes the direction of each stroke to change gradually between the two extremes of the guiding quadrant *H*, Fig. 2: so that the end of the tool, instead of moving backwards and forwards always in the same line, is worked successively over every portion of the floor of the furnace within the range marked by the dotted lines on the plan, Fig. 4, in lines radiating from the working hole in the door of the furnace, corresponding exactly to the action in hand puddling. In the double furnace, with a door on each side, the two traversing cranks *KK* are set at right angles to each other, so that the two rabbles are always working in different parts of the furnace. The whole of the machinery is kept clear above the furnace, outside and completely protected from the heat, and quite out of the way of the men; nothing being exposed to the heat except the rabble or puddling tool, the same as in hand puddling.

The double furnace shown in the drawings is exactly the same in construction in all respects as the ordinary single puddling furnaces, except that it is made with a working door at each side, and is one foot wider inside.

When the charge of pig iron is melted and ready for the commencement of the process of puddling, the apparatus is put into action by simply dropping the notch in the handle of the rabble A, Fig. 1, on to the pin in the working arm B, which is kept continuously in motion by the horizontal reciprocating bar G working overhead. The puddler changes his tool from time to time as it becomes heated, by simply lifting the notch in the handle off the pin in the working arm, and replacing the tool with a fresh one, without stopping the machine; and when the iron begins to thicken, he takes the opportunity of each change of tool to make a few strokes by hand, in order to collect the metal from the extreme sides of the furnace into the centre, which is found to ensure the whole charge being uniformly worked. The usual time of working with the machine is about 25 minutes with ordinary forge pig iron, the tool being changed five or six times; but with grey iron the time of working is much prolonged. In the latter case the machine is especially serviceable, since the iron keeps in a fluid state much longer, and requires consequently so much more working; which causes the labour to be so much more severe in the case of hand puddling that there is great difficulty in getting the men to work any iron that is very grey. With the machine however this causes no increase of labour to the men, and only increases the time of the process.

When the iron begins to thicken, or as it is termed is "coming to nature," the machinery is disconnected without stopping it, by simply knocking out the cotter that fixes the upper end of the vertical working arm B, Fig. 1; the arm then drops out, leaving the furnace door entirely clear for the puddler to ball up the iron, which is done exactly in the same manner as in ordinary puddling furnaces, without the man being in any way inconvenienced by the machinery continuing at work overhead.

The general objects aimed at in this puddling machine have been simplicity of construction and action, and small cost both in construction and repair. The machine has nothing in it liable to get out of order, and possesses great durability in the working parts.

Also the object has been to improve the quality of the iron produced, by its being more thoroughly and uniformly worked than is done by hand labour. When the metal is in the boiling state, it is known that the more work is put into it the better is the quality of the iron produced; and this work is necessarily better done by the machine than it can be by hand, since the speed of working with the machine is one half greater, and the working is kept up uninterruptedly, without any intervals for rest such as in hand labour, during which the metal would remain stationary in the furnace.

The machine is applied to ordinary single puddling furnaces by employing simply one half of the apparatus shown in the drawings, without any alteration being required in the furnace, the frame of the apparatus being merely attached to the top of the furnace. The double furnace shown in the drawings is preferable however, as it effects a great economy in the consumption of fuel, as compared with a single furnace; and puddles double the quantity of iron in the same time. With the single furnaces at the writer's works, and charges of 5 cwts., the consumption of coal is 28 cwts. per ton of puddled bar made; but with the double furnace and charges of 10 cwts., the consumption of coal is only 17 cwts. per ton of puddled bar, being a reduction of 39 per cent. The number of heats or charges worked in the single furnace is six heats of 5 cwts. each, and in the double furnace five heats of 10 cwts. each, per turn of from 9 to 10 hours. In working the double furnace it is found best to have one puddler only and two underhands, to avoid the division of responsibility that would arise in the case of two puddlers working the same charge of iron.

The yield of iron in working 5 cwts. charges in the single furnaces is 18 cwts. 2 qrs. 21 lbs. per ton of pig, or $93\frac{1}{2}$ per cent.; and with the double furnace working 10 cwts. charges the yield is 18 cwts. 2 qrs. 9 lbs. per ton of pig, or 93 per cent.

The CHAIRMAN regretted that Mr. Bennett was unexpectedly prevented from attending the meeting; but the manager of his works, Mr. Fisher, was present, and would be happy to afford any further information that was desired respecting the puddling machine. He understood that the machine had been tried at the Old Park Iron Works, Wednesbury, and enquired what had been the experience of its working there.

Mr. P. BARKER replied that they had had two of the puddling machines described in the paper at work at the Old Park Iron Works during the past two months, with very satisfactory results. The machines worked 5 cwts. of iron at each charge, instead of 4 cwts. previously worked by hand, and with the same amount of fuel; they had been worked only in the day at present, as there had been no occasion yet to work them constantly both night and day. As far as the work done was concerned, the present machine had been found very good indeed; but he thought the construction was rather complicated, and hardly strong enough to stand the rough usage that any machinery must be expected to meet with in connection with the operation of puddling. He had recently seen also a puddling machine at Mr. Eastwood's works at Derby, which worked an ordinary rabble in a somewhat similar manner; and thought that machine appeared to have a superiority in respect of strength and durability.

Mr. HENRY MAUDSLAY observed that if the machine described in the paper were found too light for durability in any parts, it might easily be made stronger to any extent desired. It appeared to him to be a well designed machine for the purpose, with a simple and direct action for working the rabble equally and regularly over all parts of the furnace. He enquired what had been found to be the durability of the machines at the Wombridge Iron Works.

Mr. W. FISHER replied that the puddling machines had now been at work constantly during the day for the last six months at the Wombridge Iron Works, and continued to work as well now as they did when they were first started; and there had been no occasion to repair any of the working parts since then, as the machines had been found very simple and strong. A man went

round twice a day, and put a little oil on morning and evening; and they could be worked night and day when desired. At first there had been a little difficulty in introducing the machine; but now the men felt its advantage, and were anxious to have it employed on night work also.

The six months' experience of the working of the machine had shown that 5 cwts. of iron were puddled by it in the time that a man would take to puddle 4 cwts.; and it was also found that the machine made a great improvement in the quality of the iron. This was accounted for by the fact that, while in hand puddling there was the liability of the underhands frequently neglecting their work, the machine went steadily on, working the tool constantly to and fro in the furnace without any intermission, and kept the iron well stirred during the whole time that the work was required to be put into it. The consequence was that very seldom was a bit of raw iron seen from the puddling furnaces worked by the machine; and the puddled bars were very seldom found to break off short in the rolling, unless the iron were a little too hot. In the heavy operation of puddling it was impossible for any puddler to stand up to his work as the machine did, since the machine never tired, but kept on steadily at the work without rest, and at a quicker rate of working than in hand puddling. By using the machine to do the heavy part of the work, it was only required for the puddler occasionally to disengage the tool and draw the iron from the sides of the furnace into the centre, leaving the machine during the rest of the time to perform its work alone. When the iron was ready for balling up, the puddler came fresh to the work; and from the men being relieved of the severest part of the labour, the furnaces worked by the machine turned out about 5 cwts. at each heat and six heats during the day, with the same quantity of fuel as was used for the ordinary heats of only 4 cwts. in hand puddling with six heats per day. The average result of the day's work with the machine was about $28\frac{3}{4}$ cwts. of puddled iron from 30 cwts. of pig iron, as compared with about $22\frac{1}{4}$ cwts. of puddled iron from 24 cwts. of pig iron by hand puddling. The improvements effected by the machine were therefore that it produced a better quality of iron with a

decreased consumption of fuel, and turned out more iron in the same time. The machine did not interfere with the wages of the underhands, as they had to be employed the same as without the machine; whilst the puddler's wages were increased by his being enabled to turn out more iron in the same time.

The CHAIRMAN enquired how many of the puddling machines described in the paper there were at work, and what was the longest time that any one had been in use.

Mr. W. FISHER replied that they had six of the machines now at work at the Wombridge Iron Works, and there were also two at the Old Park Iron Works, Wednesbury, one at the Horsehay Iron Works near Wellington, three or four in the North of England, and about a dozen in South Wales. The longest had now been at work nearly twelve months. In the first machine the traversing motion of the guiding quadrant was given by a rack and pinion reversed by a mangle motion; but this was now replaced by the crank motion shown in the drawings, which was a simpler arrangement.

Mr. F. SMITH enquired whether it was necessary for the puddling furnaces to be placed in any particular position, in order that the machines might be employed to the best advantage. At the Earl of Dudley's new ironworks at Round Oak, the puddling furnaces were placed in a semicircle, which was considered the most eligible arrangement: and he did not see how the mode of working the machines by means of a long bar driven by a crank, as described in the paper, could be made applicable in that case.

Mr. W. FISHER replied that the best arrangement as regarded the working of the puddling machines was to place the furnaces back to back in pairs, and then the single long bar running from end to end of the forge would work as many pairs of furnaces as were placed under it.

Mr. SAMPSON LLOYD observed that in regard to the circular arrangement of the puddling furnaces the adoption of small donkey engines for working each machine or each pair of machines would completely obviate all difficulty, and would allow of placing the puddling machines in any positions that might be desired, while the difference of cost would be comparatively little.

Mr. W. MATHEWS remarked that there were three essential points to be considered in connection with the application of machinery to puddling: namely, the quality of the iron produced, the quantity of the yield, and the saving of fuel; and he enquired whether the use of the puddling machine materially affected the quality of the puddled bar produced, under the same conditions that applied to ordinary hand puddling, with a reasonable proportion of grey iron supplied to the puddling furnace for each charge.

Mr. W. FISHER replied that, whilst with hand puddling the puddled bar broke very short and the general quality was indifferent, the iron puddled by the machine was much superior in quality, strong and fibrous. The yield was much greater in puddling by the machine, as there was less liability of the pig iron being burnt in the furnace for want of regular stirring; and in respect to saving of fuel, a heat of grey iron was now puddled by the machine with the same amount of fuel that was required in hand puddling for a heat of only common forge pig.

Mr. W. MATHEWS remarked that if this were the case, and if there were no inconvenience in making the machine as strong as might be found necessary to ensure its durability, there appeared no doubt that very important advantages would result from the substitution of the machine in place of hand puddling, particularly in rendering the masters independent to a great extent of puddlers. The application of mechanical means to puddling had been attended with so many difficulties that it had not been practically accomplished hitherto, and the puddlers had thus been virtually able to make their own terms with their employers; and how the latter were to get out of this difficulty was a question of great importance at the present time. The extension of commercial operations had far outstripped the increase of population, and he therefore did not anticipate that the introduction of puddling machines would in any material degree deprive the puddlers of employment; since, notwithstanding the extent to which machinery had been already substituted for manual labour in all branches of industry, the demand for labour was as a rule constantly in excess of the supply. He accordingly looked with a great deal of interest on the puddling machine, as

tending to advance the social condition of the men as well as to solve a great difficulty for the masters, and should do all he could to aid its introduction and adoption in general use: and he intended to take an early opportunity of seeing it in operation at the works where it was already employed.

Mr. G. BEARD thought the mode of working the rabble in the puddling machine shown in the drawings was by too rigid a connection: and he enquired whether any difficulty had been met with on that account when the puddler happened to put rather too much fettling into the furnace, from the tool disturbing the fettling. The successful management of the fettling was a very important element in the working of puddling furnaces, that the iron might not be put in the furnace before the fettling was properly melted, and that the fettling might not be disturbed by the rabble in working; since if any of the fettling got into the iron, it could never be separated from it. There would also be a risk he thought of a rigid tool raking the iron over the fore plate and wasting the metal, which would not be the case with a more elastic tool and a man guiding it. At the Regent Iron Works, Bilston, he had three of Griffiths' puddling machines at work, and had at first found a difficulty owing to the rigidity of the arm working the tool, which caused the tool to pull out the fettling; but this had now been overcome by using a lighter suspending hanger for working the tool, so that the tool travelled only the required length of stroke, and the elasticity of the hanger allowed it to spring a little at either end of the stroke whenever necessary; and the tool was moreover guided by a man during the whole time of working.

His own experience of the results of puddling by machinery was that it was a decided improvement in all respects. The first advantage gained was that the quality of the iron made was improved, by its being worked with much greater regularity than a man could work it, and it was much cleaner by the time it was ready for balling up. He had found the iron puddled by the machine was as good as that worked by hand when the pigs used with the machine were 3s. or 4s. per ton less in price than those used in hand puddling. Another advantage was that much larger quantities

could be puddled by the machine and with a smaller quantity of coal: at his own works the quantity of iron worked by each of the three puddling machines was 6 cwts. per heat, and five heats per turn, and he saw no reason why the make should not be increased to 2 tons per turn from each furnace, by working larger heats. At present however the men got out the iron much better in working 6 cwts. heats than they would do with heavier charges. The rate of wages paid to the men was the same with the machines as in hand puddling.

Mr. W. FISHER explained that in the machine described in the paper the rabble had two nicks made in it at about 6 inches distance apart, either of which could be shipped over the pin of the arm working the rabble, according to the distance to which the tool was required to be worked in the furnace. On first starting a fresh heat after fettling the furnace, the tool was first worked at its shortest length by means of the inner nick, so as not to travel so far towards the back of the furnace; and afterwards it was changed to the other nick for working to its full distance in the furnace. There was no risk of the tool disturbing the fettling in working, as the rabble merely rested loosely with its weight upon the bottom of the furnace, just the same as in hand working. A great deal of responsibility rested upon the man attending to the machine, as regarded the proper condition of the fettling, and great care was necessary on the part of the foreman to see that this was properly looked after. The furnace should be well heated and the fettling melted and well knocked up before the charge was allowed to be put in; for if the fettling were simply thrown in and not properly broken up and melted, it was of course likely to get mixed with the iron in puddling: but when well knocked up in the first instance, while hot and soft, it was found to stand as well as if it had been laid on with a trowel.

In reference to the quantity of iron in the charges, they had worked 6 cwts. charges with the machine at the Wombridge Iron Works in the same time as 5 cwts., and in less time than the usual 4 cwts. heats puddled by hand labour; and he had no doubt 6 cwts. would ultimately be reached as the regular charge with the machines

wherever they were employed. At first there had been a difficulty in getting the men to work more than five heats in the day, and they were allowed to remain at that ; but when one man had succeeded in working six heats per day regularly, the others wanted to get as much out of their furnaces, and found they could readily do it ; and six heats per day was now the regular make of each of the furnaces worked by the puddling machines. He should be happy to show the working of the machines at any time, as they were in regular work every day.

The CHAIRMAN proposed a vote of thanks to Mr. Bennett for his paper, which was passed.

The Meeting then terminated.
